

Compendium of Transgenic Crop Plants

Volume

Transgenic Cereals and Forage Grasses

Editors Chittaranjan Kole and Timothy C. Hall

Volume 1: Transgenic Cereals & Forage Grasses

1. Rice
2. Maize
3. Wheat
4. Barley
5. Oat
6. Sorghum
7. Pearl millet
8. Finger Millet
9. Cool Season Forage Grasses
10. Bahia Grass

Volume 2: Transgenic Oilseed Crops

1. Soybean
2. Oilseed Brassicas
3. Sunflower
4. Peanut
5. Flax
6. Sesame
7. Safflower

Volume 3: Transgenic Legume Grains and Forages

1. Common bean
2. Cowpea
3. Pea
4. Faba Bean
5. Lentil
6. Tepary Bean
7. Asiatic Beans
8. Pigeonpea
9. Vetch Pea
10. Chickpea
11. Lupin
12. Alfalfa
13. Clovers

Volume 4: Transgenic Temperate Fruits and Nuts

1. Apple
2. Pears
3. Peach
4. Plum
5. Berries
6. Cherry
7. Grapes
8. Almond
9. Persian Walnut

Volume 5: Transgenic Tropical and Subtropical Fruits and Nuts

1. Citrus Fruits
2. Grapefruit
3. Banana
4. Pineapple
5. Papaya
6. Mango
7. Avocado
8. Kiwifruit
9. Passion Fruit
10. Persimmon

Volume 6: Transgenic Vegetable Crops

1. Tomato
2. Egg plant
3. Capsicums
4. Vegetable Brassicas
5. Radish
6. Carrot
7. Cucurbits
8. Alliums
9. Asparagus
10. Leafy Vegetables

Volume 7: Transgenic Sugar, Tuber and Fiber Crops

1. Sugarcane
2. Sugar beet
3. Stevia
4. Potato
5. Sweet potato
6. Cassava
7. Cotton

Volume 8: Transgenic Plantation Crops, Ornamentals and Turf Grasses

1. Tobacco
2. Coffee
3. Cocoa
4. Tea
5. Rubber
6. Medicinal Plants
7. Ornamentals
8. Turfgrasses

Volume 9: Transgenic Forest Tree Species

1. Poplars
2. Eucalypts
3. Pines
4. Spruces
5. Chestnuts
6. Birches
7. Douglas-fir
8. American Elm
9. Black Walnut
10. Casuarinaceae
11. Black Locust
12. Sandalwood
13. Teak

Rice is Life

—Theme of UN International Year of Rice, 2004

*Cutting stalks at noon time Perspiration drips to the earth
Know you that your bowl of rice Each grain from hardship comes?*

—Cheng Chan-Pao, Chinese Philosopher

1. INTRODUCTION

Rice serves as the principal source of nourishment for over half of the global population and vies with wheat and maize as the most important cereal crop. As a symbol of life, prosperity, fertility, and self-sufficiency, it is deeply embedded in the cultural heritage of many societies. The global importance of this crop reached its pinnacle on the occasion of the 57th session of the United Nations General Assembly, when the Food and Agricultural Organization declared the year 2004 as the International year of Rice (FAO, 2004). This unprecedented step in United Nation's history of devoting a year to a commodity was based on the need to heighten awareness of the role of rice in alleviating global poverty and malnutrition. The declaration was also aimed at "the need to focus world attention on the role that rice can play in providing food security and eradicating poverty in the attainment of the internationally agreed development goals" (UN Declaration, 57th Session, 2004).

Rice accounts for more than one-fifth of the calories consumed by human beings in their global diets (Smith, 1998). In Asia, rice and its derivatives account for 60–70% of energy intake for over 2 billion people (FAO, 2004). As an important commercial crop, it is the most rapidly growing food source in Africa and is of significant importance to food security in an increasing number of low-income food-deficit countries. Rice-based production systems and their associated postharvest operations employ nearly 1 billion people in rural areas of developing countries, and about four-fifths of the world's rice is grown by small-scale farmers in low-income countries (FAO, 2004). The production of 700 million metric tons (FAO data for 2005) makes rice the world's largest seed crop, closely followed by maize and wheat.

1.1 History, Origin, and Distribution

The word *rice* is believed to be of Indo–Iranian origin, the term being derived from the Tamil word

Arisi and the Arabic *Ar-ruzz*. The English origins are attributed to Greek *Ōryza*, via Latin *Oriza*, Italian *Riso*, and the Old French *Ris* (Wikipedia, 2007).

Cultivation of rice is thought to have originated along the Yangtze Delta, one of the cradles of East Asian civilization in China. Paleobotanical hypothesis credits the Chinese of the Late Pleistocene era with collecting wild rice, leading to its eventual domestication about 6400 BC (Zhao, 1998). Early Neolithic groups are also known to have cultivated rice, possibly as early as 9000 BC with radiocarbon dating evidence going back to at least 7000 BC (Crawford and Shen, 1998; Diamond, 1999; Zohary and Hopf, 2000).

The oldest scriptures in India mention rice (the term used was *Dhanya*), rice dishes, and aspects of rice cultivation (Nene, 2005). Farmers practiced mixed farming techniques planting the rice crop in integrated fields during the Indus Valley Civilization (Kahn, 2005). Wild rice appeared as early as 5440 BC in the Belan and the Ganges valleys of northern India. Along with barley, meat, dairy products, and fish, rice was a dietary staple of ancient Dravidian society (Taylor, 2004).

Dryland rice was introduced to Japan and Korea between 3500 and 1200 BC (Crawford and Lee, 2003). Wetland cultivation techniques migrated to Indonesia around 1500 BC and then to Japan by 100 BC. The Niger River delta extending to Senegal was the rice farming region in Africa during 1500–800 BC. The Moor invasion of the Iberian Peninsula in 700 AD introduced rice to Spain, from whence it spread during the 15th century through Italy and France to all continents during the great age of European exploration (Wikipedia, 2007). Rice arrived in North America in 1694, from Madagascar to South Carolina. Plantation owners in Georgetown, Charlestown, and Savannah learnt techniques of rice culture such as dyking of marshes and periodical flooding of fields from African slaves, who also brought with them rice mills made of wooden paddles and winnows made of sweetgrass baskets. Subsequent improvements in rice production can be attributed to the invention of rice mill and the addition of waterpower to these mills. The predominant strains of rice in Carolina were christened “Carolina Gold” (Wikipedia, 2007).

Plants of the genus *Oryza* are known to thrive in desert, hot, humid, flooded, dry, and cool

conditions, and grow in saline, alkaline, and acidic soils. There are 24 species of *Oryza*. Domesticated or cultivated rice comprise two main species, the Asian rice *Oryza sativa*, and the African rice *Oryza glaberrima*. *O. sativa* was domesticated from wild Asian rice, *Oryza rufipogon*, originating in the foothills of the Himalayan mountain ranges, with *O. sativa* var. *Indica* of India and *O. sativa* var. *Japonica* from China and Japan (Londo *et al.*, 2006). *O. sativa* cultivars consist of three groups: the short-grained “*Japonica*” or “*Sinica*” (e.g., Japanese rice); long-grained “*Indica*” varieties (e.g., *Basmati* rice); and the broad-grained “*Javanica*” rice (e.g., Jefferson rice) (Zohary and Hopf, 2000).

Originating from its Asian homeland, rice shows a diverse distribution and is cultivated in 113 countries and 6 continents (none in Antarctica!). Rice is grown under a wide range of soil moisture regimes, from deep flood to dry land, and in various soil conditions. Rice-based production systems span from 53°N, in the Heilongjiang Province of China, to 35°S in New South Wales of Australia; from the tropical rain forest climate of the Congo to the continental temperate climate in Krasnodar of Russia; from the arid desert climate found in Egypt’s Nile Delta, to the sea-level regions in Guinea-Bissau, to 2700m above sea level as in the Himalayan mountain chains in Nepal and India (FAO, 2004).

1.2 Botanical Description

1.2.1 Scientific classification

Kingdom: Plantae
 Division: Magnoliophyta
 Class: Liliopsida
 Order: Poales
 Family: Poaceae
 Genus: *Oryza*
 Species: *O. glaberrima* and *O. sativa*

1.2.2 The plant

Rice is a semiaquatic, monocarpic annual grass plant, its height varying from 0.6 to 1.8 m (2–6 ft.) tall. The plants tiller, i.e., develop multiple shoots, depending on the variety, spacing, and soil fertility.

The grass has long, slender leaves 50–100 cm long and 2–2.5 cm broad. The small wind-pollinated flowers are produced on a branched arching to pendulous inflorescence 30–50 cm long. The inflorescence is an open panicle. Flowers are distinct in having six anthers as opposed to the commonly seen three anthers in other grasses. Spikelets have a single floret, lemma, and palea enclosing a grain (caryopsis) 5–12 mm long and 2–3 mm thick that can be yellow, red, brown, or black. The lemmas may be awnless, partly or fully awned. The rice kernel has four primary components: the hull or the husk, the seed coat or bran, the embryo or germ, and the endosperm. Rice milling procedures yield a variety of products depending on the extent of outer layer removal. If just the inedible husk is removed, it results in brown rice where, the nutritious high-fiber bran is a source of 8% protein, iron, calcium, and B vitamins. Removal of the bran and germ results in white or polished rice, which is greatly diminished in nutrients.

1.2.3 Habit and habitat

The ideal climate for rice growth is 75 °F (24 °C). Its growth cycle is 3–6 months. In nonindustrialized nations, rice fields are typically prepared by ploughing (by cattle-drawn ploughs or a tractor), fertilizing (traditionally with dung or sewage), and smoothing (a process of dragging a log across the field). Seedlings are prepared in seedling beds, and after a month, are transplanted manually to the fields, which have been flooded by rain or river water. Dike-controlled canals or manual watering maintains irrigation during the entire growth period. Before harvesting the crop, the fields are allowed to drain.

1.2.4 Genome

Evolutionary lineages of major flowering plants, monocots, and dicots, as illustrated by rice and *Arabidopsis*, were shown to have diverged about 200 million years ago. The genomes of these two plants do not share extensive synteny, but similarities exist amongst many encoded proteins. Rice genes diverge from *Arabidopsis* in guanine-

cytosine (GC) content, codon usage, and amino acid usage. There is also a gradient in the GC content of rice genes that is not seen in *Arabidopsis* genes, with the 5' end being up to 25% richer in GC content than the 3' end.

The draft genome sequences of both *Indica* rice (Yu *et al.*, 2002) and *Japonica* rice (Goff *et al.*, 2002) were published in the same year. These analyses gave an average gene size of 4.5 kb with some 513 ribosomal RNA gene repeats and 688 centromeric repeats. The average rice genome is a compact 430 Mb, one-sixth the size of the human and maize genomes (Leach *et al.*, 2002). It is the smallest of all genomes amongst grasses, commonly grown as crops. The smaller genome is reflected in a higher gene density relative to other cereals, with an average of one gene every 15 kb (Goff, 1999). However, the overall organization of genes is preserved in such a way that rice genomic information can be used as a useful guide in deciphering the larger genomes of maize and barley. The genomic similarity makes it possible to approximate the genomes of these grain species in a concentric circle, and use the smaller rice genome as a guiding point to find related genes of interest in the larger genomes (Figure 1).

The characteristics of rice genome are summarized in Table 1 (Goff *et al.*, 2002; Yu *et al.*, 2002).

Figure not available

Table 1 Salient features of the rice genome^(a)

Rice strain	Indica	Japonica
Genome size (Mb)	466	420
Number of genes	46–56 K	32–50 K
Duplicated genes (%)	74	77
Number of transposable elements	>24.9%	4220
Number of single sequence repeats	1.7%	46 666

^(a)Reproduced from the Rice Genome Poster (2002)

1.2.5 Cytological features

O. sativa L. has a chromosome number of $2n = 24$ (Kuwada, 1910). The DNA content was determined to be 0.87–0.96 pg/2C (Martinez *et al.*, 1993). In contrast to the rapid progress in molecular analysis, progress in cytological characterization of the rice genome has had limited success. Early studies using fluorescent *in situ* hybridization techniques to map DNA sequences on chromosomes (Fukui *et al.*, 1994; Jiang *et al.*, 1995; Ohmido *et al.*, 1998) involved mapping on mitotic metaphase chromosomes. This approach provided limited details due to low mapping resolution. Cheng *et al.* (2001a) successfully used pachytene chromosome karyotyping by hybridizing 24 bacterial artificial chromosome (BAC) clones and a rice centromere DNA-specific probe with all 24 chromosomal arms. The arm-specific BAC clones unambiguously identified rice chromosomes in both mitotic and meiotic cells at $2n = 24$. The longest was chromosome 1 (61.12 μm) and the shortest was chromosome 10 (24.74 μm), the descending order of chromosome length being 1, 3, 2, 6, 4, 5, 7, 8, 11, 9 (not including the ribosomal DNA (rDNA)), 12, and 10. Heterochromatic regions that have a high AT content relative to euchromatic regions were preferentially stained by DAPI (4', 6-diamidino-2-phenylindole). Chromosomes 4 and 10 have the most distinct heterochromatic patterns, with one-third of the chromosome, including the entire short arm and part of the long arm, being highly heterochromatinized. Other heterochromatic regions were the pericentric region of chromosome 5, the distal region of the long arm of chromosome 11, and the short arm and pericentric region on the long arm of chromosome 10. The three longest chromosomes (1, 2, and 3) are more euchromatic than the others.

1.3 Economic Importance

1.3.1 Production and trade

Rice has a key role in the food security of the world. In 2005, world rice production reached a record level of 621 million tons (FAO, 2005). Much of the expansion was concentrated in Asia, with mainland China boosting production by 6 million tons compared to the previous year. Large increases were also reported from Bangladesh, India, Myanmar, Pakistan, Sri Lanka, and Thailand. Developing countries account for 95% of the total world rice production, 83% of exports, and 85% of imports, with China and India accounting for more than 50%. According to FAO fact sheets, global trade in rice grew at 7% a year throughout the 1990s.

The top 10 rice-producing countries in terms of metric tons are as in Table 2 (FAO, 2004).

1.3.2 Nutrition

Rice provides 20% of the world's dietary energy supply, and is followed by wheat (19%) and maize (5%) (FAO, 2004). Rice is a good source of thiamine, riboflavin and niacin. Brown rice is a good source of dietary fiber. The overall amino acid profile for rice seed shows high values for glutamic and aspartic acid, with lysine as the limiting acid. Rice has a rich genetic diversity with over 1000 varieties and its natural colors include brown, red, purple, and black. Nutrient contents of these varieties are summarized in Table 3.

Rice is an integral part to the culinary traditions of many cultures with personal preferences regarding texture, taste, color, and stickiness. Dry

Table 2 Top 10 rice producers^(a)

Country	Metric tons
1. China	166.0 $\times 10^6$
2. India	133.5 $\times 10^6$
3. Indonesia	51.8 $\times 10^6$
4. Bangladesh	38.0 $\times 10^6$
5. Viet Nam	34.6 $\times 10^6$
6. Thailand	27.0 $\times 10^6$
7. Myanmar	21.9 $\times 10^6$
8. Philippines	13.2 $\times 10^6$
9. Brazil	10.2 $\times 10^6$

^(a)Reproduced from FAO (2004)

Table 3 Nutrient contents of rice varieties^(a)

Type of rice	Protein (g/100 g)	Iron (mg/100 g)	Zinc (mg/100 g)	Fiber (g/100 g)
White	6.8	1.2	0.5	0.6
Brown	7.9	2.2	0.5	2.8
Red	7.0	5.5	3.3	2.0
Purple	8.3	3.9	2.2	1.4
Black	8.5	3.5	—	4.9

^(a)Reproduced from FAO Rice Fact Sheet: Rice and Human Nutrition (2004)

flaky rice is preferred in South Asia and the Middle East; moist sticky rice in Japan, Taiwan, Korea, Egypt, and northern China; red rice and long-grained scented rice in India. Many countries have signature recipes such as *sushi* (Japan), fried rice, *pulav*, and *biryani* (India), *paella*, *risotto*, and *pancīt* (Italy).

1.4 Traditional Breeding: Breeding Objectives, Tools and Strategies, and Achievements

The science of plant breeding has been developed mainly in the 20th century. However, as a practice it goes back thousands of years when art and science as we know them now, were a unified learning process for enhanced survival. Archaeological finds in India and China indicate the beginning of rice cultivation from earlier than 10 000 years ago (Chang, 2000). Starting from India and China, the dispersal and selection of ancient varieties of *O. sativa* in South-East Asia, Austronesia, and Africa date back to 5000 years. At present, rice is the staple food of nearly half of the world population. Nearly 90% of all rice is grown in Asia with China and India together accounting for nearly one-third of the total global production of 618 million tons in 2005 (International Rice Research Institute, 2006). Only a little more than 5% of the global rice production is traded in international markets indicating its importance in feeding the domestic population. Since after the Second World War, there has been an exponential growth in population and in the number of people below poverty line in Asia and Africa. Hence, through major international research initiatives, rice breeding efforts have targeted the increase of rice yield. The Rice Development Program of FAO recommends “increases in rice production in all

ecologies—from high altitude to coastal areas and from temperate to tropical climates.” Various rice breeding efforts globally have directly or indirectly aimed at increasing the rice yield to support the unprecedented growth in population.

1.4.1 Breeding objectives

1.4.1.1 Abiotic stress resistance

This includes drought, salinity, waterlogging, cold and frost, soil pH, mineral deficiency, and toxicity.

1.4.1.2 Biotic stress resistance

This includes the following:

- (a) Major pests such as yellow stem borer (*Scirpophaga incertula*), gall-midge (*Orseolia oryzae*), brown planthopper (*Nilaparvata lugens*), white-backed planthopper (*Sogatella furcifera*), green leafhopper (*Nephotettix*), striped stem borer (*Chilo suppressalis*), rice leaf folder (*Cnaphalocrocis medinalis* and/or *Marasmia exigua*).
- (b) Major pathogens such as bacterial blight (*Xanthomonas oryzae*), sheath blight (*Rhizoctonia solani*), fungal blast (*Magnaporthe grisea*), fungal stem rot (*Sclerotium oryzae*), root-knot nematode (*Meloidogyne*), rice dwarf virus, rice grassy stunt virus (RGSV), rice hoja blanca virus (RHBV), rice yellow mottle virus (RYMV), and rice tungro virus (RTD).

1.4.1.3 Other agronomic traits

Other major agronomic traits include: lifecycle time, weed competitiveness, nitrogen (and other

macronutrient) uptake and utilization, plant height, number of tillers and panicles, photoperiod sensitivity, flowering time, wide compatibility, male sterility and/or self-incompatibility, fertility restoration, grain number, weight, size, shape, fragrance, composition, and nutritional quality including starch, proteins, macro- and micronutrients.

1.4.2 Breeding tools and strategies

According to Khush and Brar (2002) the tools and strategies used to achieve the above objectives can be divided into two phases, the evolution phase or broadening the gene pool of rice cultivars, whereby rice populations are created that can serve as selection stocks and the evaluation phase or increasing selection efficiency, whereby superior genotypes are selected.

1.4.2.1 Evolution phase

The following approaches have been used to expand the genetic pool of rice:

- (a) *Wide hybridization* refers to creating hybrids between the cultivated species of *O. sativa* containing the AA genome and any one of the wild variety represented by 24 species containing any one of the 10 possible genome compositions (AA, BB, CC, BBCC, CCDD, EE, FF, GG, HHJJ and HHKK). The strategy of embryo rescue has been successfully used to transfer a number of genes for resistance to insect pests and pathogens from the wild species into the cultivated species creating nuclear genome diversity (Jena and Khush, 1990; Khush *et al.*, 1990; Brar and Khush, 1997). Additionally, Lin and Yuan (1980) created cytoplasmic diversity when they successfully used the nucleus of the cultivated *O. sativa* and cytoplasm of the wild *O. sativa* L. f. *spontanea*. This hybrid has been the source of cytoplasmic male sterility in the highly successful Chinese hybrid rice programs.
- (b) *Somaclonal variation* refers to genomic changes created by dedifferentiation and

regeneration cycle of the tissue culture protocols. It serves, as a method for natural selection of mutations since *in vitro*-regenerated plants must retain genome functionality to give rise to a largely normal plant. The technique was successfully used to create a variety with superior cooking qualities and increased resistance to rice blast (Araujo and Prabhu, 2002).

1.4.2.2 Evaluation phase

The following methods are used for efficiently selecting for desired characteristics:

- (a) *Field-based evaluation* on hybrids or variants generated through embryo rescue or tissue culture, respectively was the main route of selection of desired phenotype in the conventional breeding methods. However, the process of evaluating and selecting the desired phenotype also now starts in the laboratory, for example, anther culture can be used to generate doubled haploid (DH) plants that serve as true breeding lines thus shortening the time toward generating a new variety (Khush and Brar, 2002). Selection efficiency of DH lines is higher if dominance variation as evidenced through a number of new varieties developed using DH lines (Khush and Brar, 2002).
- (b) *Molecular genetics based evaluation* is now the norm since DNA markers have highly facilitated the tracking of characters through crosses and generations. Although the methods have not been extensively used on wide hybrids or somaclonal variants, they have been very useful in tagging and tracking rice fungal blast and bacterial blight resistance quantitative trait loci (QTLs) through various crosses (Young, 1996). Various molecular markers are now available for use such as restriction fragment length polymorphism, amplified fragment length polymorphism, random amplified polymorphic DNA, simple sequence repeats, single nucleotide polymorphisms, etc. Semagn *et al.* (2006) provide a good review of the different molecular markers used in plant breeding, the

principles on which these are based, limited information on laboratory protocols and the advantages of each. Additionally, Khush and Brar (2002) provide a detailed account and examples of how rice breeding efforts have been positively affected by efficient selection using molecular marker technology, molecular maps, synteny relationships, marker-aided selection, QTL mapping, gene tagging and gene pyramiding, map-based cloning, and functional genomics.

Laboratory based techniques, such as the wide hybridization and embryo rescue, anther culture, somaclonal variation, and molecular markers may have indeed hastened the process of selection and reduced the time to generating a new variety, yet substantial advances and achievements were made using classical breeding systems of pedigree and bulk methods, three-way remote crosses, recurrent parent, and rapid generation advancement. The chromosomal deletion lines, recombinant inbred lines, near isogenic lines, and pure lines were made available through sheer diligence and perseverance in the fields. These methods were facilitated then by ethylmethane sulfonate (EMS)- and radiation-mediated mutation. Creation of semidwarf varieties, resistance to certain pests and pathogens, and maintaining cytoplasmic and genic male sterility were all achieved through classical breeding. By mid 1980s the rice production was double that of mid 1950s. Nearly half that improvement was due to additional land being cultivated but the other half was due to high-yielding varieties developed through conventional breeding methods. The achievements of conventional plant breeding have been reviewed at regular intervals (Bingham, 1981; Duvick, 1986; Reeves and Cassaday, 2002).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

A major constraint of conventional breeding approaches is the nonavailability of desirable genes within the gene pool, for example in rice, there is limited variability for resistance to diseases such as sheath blight, stem borer, and other insect pests, bacteria and fungi contain genes,

such as the *Bacillus thuringiensis* crystal proteins (*Bt Cry*) and chitinase, respectively, which can be useful against pests and pathogens. Transferring genes from one kingdom to another invokes for transgenic approaches. A variety of *Bt* genes have been transferred to rice using electroporation, biolistic or *Agrobacterium*-mediated transformation methods (Fujimoto *et al.*, 1993; Wunn *et al.*, 1996; Ghareyazie *et al.*, 1997; Nayak *et al.*, 1997; Cheng *et al.*, 1998; Maqbool *et al.*, 1998, 2001; Tu *et al.*, 2000). In cases when genes are available within the gene pool of rice for transfer to cultivated varieties, conventional breeding methods suffer from drawbacks such as hybridization barriers, low selection efficiency, and long breeding cycles that take a long time to generate a new variety. Transgenic approaches along with methods such as anther culture and marker-assisted breeding can overcome these limitations. Additionally, the genes available within the gene pool may not be expressed at desirable levels or may not have the desirable expression patterns, thus needing modification of regulatory elements. Such modifications and the downstream incorporation of the gene into the genome are possible only through transgenic approaches. For example, the endogenous rice chitinase gene was modified to constitutively express at higher than endogenous levels under the CaMV 35S promoter, conferring enhanced resistance to sheath blight (Lin *et al.*, 1995).

Introducing designer characteristics in modifying the nutritional quality and quantity of rice grains or having genes expressed at specific time and place of the plant life cycle also calls for transgenic approaches. For example, in the case of “Golden Rice”, enriching the rice grains with β -carotene was possible by expressing three genes responsible for provitamin A synthesis (Ye *et al.*, 2000). Rice anther specific expression of a gene isolated from anther complementary DNA (cDNA) was confirmed through transgenic plants. The gene is responsible for male fertility and hence, important in hybrid rice programs (Luo *et al.*, 2006).

Molecular markers have fast-tracked plant breeding. Similarly, molecular approaches to creating mutant lines using transgenic approaches with transposons or transfer DNA (T-DNA) have fast-tracked mutation detection. Either a known

gene of interest is examined for function and/or expression patterns or novel genes are identified through this approach. The added advantage of these approaches is that a genome saturated insertion-mutation library can be created and stored. Such a library represents a population of seeds with insertion mutation in every single gene, ideally one gene mutation per seed, so that any changes in the plant arising from such a seed can be tracked to changes in that one mutated gene. Such libraries have been created for rice using an endogenous retrotransposon (Hirochika, 2001; Miyao *et al.*, 2007), heterologous maize *Ac* or *Ac/Ds* transposon (Enoki *et al.*, 1999; Kohli *et al.*, 2001, 2004; Kolesnik *et al.*, 2004; Upadhyaya *et al.*, 2006), and the T-DNA (Jeon *et al.*, 2000; Chen *et al.*, 2003; Sallaud *et al.*, 2003; An *et al.*, 2005a, b; Fu *et al.*, 2006; Liang *et al.*, 2006). A number of novel genes have been identified using insertional mutations. Recently, a dwarf mutant gene was identified from the T-DNA tagged population (Zhou *et al.*, 2006). In a comprehensive review on advances in rice biotechnology, Kathuria *et al.* (2007) list other genes identified and isolated through molecular tagging approaches. These include genes involved in gibberellic acid biosynthesis (Margis-Pinheiro *et al.*, 2005), blast resistance (Kim *et al.*, 2003), tapetum development (Jung *et al.*, 2005), and pollen development (Han *et al.*, 2006).

2. DEVELOPMENT OF TRANSGENIC RICE

In the 1960s, doubling of the world's population to more than 6.4 billion, together with a drastic decrease in cultivated land led to a global food crisis. However, a Nobel Peace Prize winning effort by Norman E. Borlaug, now christened "the green revolution", averted a large-scale famine in the semi-arid tropics of South Asia, specifically in India, Pakistan, the Philippines, and Mexico. The introductions of high-yielding semidwarf varieties of wheat and rice, in combination with applications of large amounts of nitrogen fertilizer to increase grain yields and promote leaf and stem elongation, was crucial for the success of the first green revolution (Sakamoto and Matsuoka, 2004). The situation now comes full circle as the world population, estimated to

touch 8 billion by 2025, again looks out for strategies to increase grain production. The second green revolution calls for genetic engineering of food crops (Sakamoto and Matsuoka, 2004), and advances in transgenic rice production would be extremely beneficial toward achieving the needed goals. Parameters identified to be associated with increases in yield potential are plant height, tiller number, photosynthesis, photoperiod insensitivity, and disease and insect resistance (Khush, 1999). The green revolution genes, namely the wheat green revolution gene *Reduced height1* (*Rht1*) and the rice green revolution gene *semidwarf1* (*sd1*) have been identified and have been found to encode mutant gibberellin response modulators (Peng *et al.*, 1999). Genetic manipulations of gibberellin (GA) levels thus would prove to be a promising first step to generate semidwarf varieties that, in combination with artificial control of tillering, would lead to a dramatic increase in the yield potential of rice (Sakamoto and Matsuoka, 2004). Commercial use of transgenic rice is far less than that of transgenic maize that is now planted on more than 15 million hectares around the world (James, 2003). The ambitious 16-year-long program of the Rockefeller Foundation for rice biotechnology was a key factor in positioning rice biotechnology to be advanced to the domains of public and federal funding (O'Toole *et al.*, 2001). Sequencing of the rice genome provides added impetus to advances in transgenic rice technology, and also cements the "model monocot" status of rice. The rapid advances in rice biotechnology, starting nearly two decades ago with the production of the first transgenic rice plants (Toriyama *et al.*, 1988; Zhang and Wu, 1988) have resulted in the development of high-throughput, reproducible transformation protocols in the crop. Transgenic rice plants with improved tolerance to biotic/abiotic stresses, improved insect/pest/disease tolerance, and increased nutritional values have been developed (Upadhyaya *et al.*, 2000a; Bajaj and Mohanty, 2005; Kathuria *et al.*, 2007). Rice has also served as a model to understand the process of plant transformation in general, both in terms of transgene integration and modulation of gene expression (Kohli *et al.*, 1998, 1999a, b; Iyer *et al.*, 2000; Cheng *et al.*, 2001b; Kloti *et al.*, 2002; Vain *et al.*, 2002; Kathuria *et al.*, 2007).

2.1 Donor Genes

The need for transgenic technologies to improve the qualitative and quantitative yields and other agronomic characteristics of rice cannot be overstated. Lack of desirable genes within the rice gene pool and a consequent search for these genes in other organisms pushed the frontiers in locating, isolating and cloning heterologous genes, and designing transgene constructs for rice transformation.

The donor genes for rice transformation over the years have been isolated from different kingdoms. Examples abound for multiple genes from each kingdom that have been introduced in rice. Specific examples of a gene or a class of genes introduced in rice from each kingdom, highlighting an important agronomic or technical advance are mentioned in Table 4. The cited references for each of these genes point either to recent research or review papers or to one of the first reports in literature. Additional genes and regulatory sequences introduced in rice and their source organisms are mentioned in different sections of this chapter as directly related to the aim of generating the transgenic plants.

The donor gene sources ranging from viruses to humans, and the aims of transforming rice with these genes can be categorized as in Table 4.

2.1.1 Plant transformation

Increasingly efficient transformation, selection, and screening tools techniques and genes are a prerequisite for generating transgenic rice with improved agronomic characteristics. New selectable marker and reporter genes are continually being explored for their use in efficient selection of transformed cells/tissues or reporting transgene expression status. Increasingly these genes are chosen and designed to be neutral in terms of their substrates and products affecting the plant *per se* or the consumer. In most cases however, the effort now is to generate marker-free transgenic plants. The *hpt* and the *pat* genes have been the most frequently used selectable markers for rice transformations while the *gus* and the *gfp* genes have been the most frequently used reporter genes. Recently Lee *et al.* (2007) have

used the *Myxococcus xanthus* protoporphyrinogen oxidase (MxPPO) as an efficient selectable marker using the peroxidising herbicide butafenacil. Although the MxPPO is only an addition to the herbicide resistance class of selectable markers for rice transformation, it supplies an example of another experimentally tested system in rice. Latest comprehensive reviews on transgenic rice by Bajaj and Mohanty (2005) and Kathuria *et al.* (2007) illustrate the novel selectable markers and reporter genes used. For example, some novel and neutral selectable markers include the phosphomannose isomerase gene (Lucca *et al.*, 2001b), the α -subunit of anthranilate synthase (Yamada *et al.*, 2004); conditional negative selection with cytosine deaminase (Dai *et al.*, 2001a), indole acetic acid hydrolase (IAAH/tms2; Upadhyaya *et al.*, 2000b), aminoglycoside 3-adenyltransferase (*aadA*; Oreifig *et al.*, 2004), and D-amino acid oxidase from yeast (*dao1*; Erikson *et al.*, 2004). Modified *gus*, *gfp*, *luc*, and synthetic *sialidase* and *xylanase* in combination with *gus* used as the latest reporter genes have also been described (reviewed in Bajaj and Mohanty, 2005).

Generating marker-free transgenic rice plants has been accomplished through different strategies. For example, simple molecular analyses of the segregating population for the lack of selectable marker when it integrates separate from the gene of interest. With *Agrobacterium*-mediated transformation, the use of independent constructs to carry the marker gene and the gene of interest increases the frequency of independent integration and hence facilitates segregation in the following generations. Cleverly designed “twin T-DNA” vectors also accomplish the same (Komari *et al.*, 1996; Lu *et al.*, 2001), as does the dual binary vector system of pGreen/pSoup (Vain *et al.*, 2003). Alternatively, molecular excision of the selectable marker was achieved through site-specific recombination using *cre/loxP* (Gleave *et al.*, 1999; Moore and Srivastava, 2006), flipase recombination enzyme (FLP)/flipase recombination target (FRT) sites (Srivastava and Ow, 2004) and/or *Ac/Ds* transposon system (Cotsaftis *et al.*, 2002). Endo *et al.* (2002) used the multiauto transformation (MAT) vector containing the *Agrobacterium* isopentyl transferase (*ipt*) gene as a marker in combination with the *R/RS* site-specific recombination system to generate

Table 4 Donor genes for generating transgenic rice

Kingdom	Source	Gene	Functional category	Reference
Prokaryota	Viruses:	Class of viral genes	Viral disease resistance	Hayakawa <i>et al.</i> (1992); Sivamani <i>et al.</i> (1999); Pinto <i>et al.</i> (1999); Kouassi <i>et al.</i> (2006)
	Rice stripe			
	Rice tungro			
	Rice yellow mottle			
	Baculoviruses and Entomopoxviruses	EPV-fusolin	Insect disease resistance	Hukuhara <i>et al.</i> (1999)
	Eubacteria:	Class of <i>Bt Cry</i> genes	Insect disease resistance	Khush and Brar (2002); Bajaj and Mohanty (2005); Roh <i>et al.</i> (2007)
Protista	<i>Bacillus thuringiensis</i>			
	<i>Escherichia coli</i>	β -glucuronidase	Screenable marker	Kathuria <i>et al.</i> (2007); Terada and Shimamoto (1990)
		Trehalose biosynthetic genes	Abiotic stress resistance	Garg <i>et al.</i> (2002)
		<i>Phosphomannose isomerase</i>	Selectable marker	Lucca <i>et al.</i> (2001b)
	<i>Erwinia uredovora</i>	<i>Phytoene desaturase</i>	β -Carotene synthesis	Ye <i>et al.</i> (2000)
	—	—	—	—
Fungi	<i>Streptomyces</i>	<i>Phosphinothrycin N-acetyltransferase</i>	Selectable marker and herbicide tolerance	Christou <i>et al.</i> (1991)
		<i>Hygromycin phosphotransferase</i>	Selectable marker	Meijer <i>et al.</i> (1991)

	Daffodil	<i>Agglutinin</i>		
		<i>Phytoene synthase</i> and <i>Lycopene B cyclase</i>	β -Carotene (provitamin A) synthesis	Ye <i>et al.</i> (2000)
	Maize	<i>Phytoene desaturase</i>	Higher β -carotene synthesis	Paine <i>et al.</i> (2005)
		Anthocyanin genes	Fungal blast resistance	Gandikota <i>et al.</i> (2001)
		<i>Ribosome inactivating protein</i>	Sheath blight resistance	Kim <i>et al.</i> (2003)
	<i>Arabidopsis</i>	<i>Phytochrome A</i>	Grain Yield	Garg <i>et al.</i> (2006)
		<i>LEAFY</i>	Plant architecture and early flowering	He <i>et al.</i> (2000)
		CBF3/DREB1A/ABF3	Abiotic stress tolerance	Oh <i>et al.</i> (2005)
		<i>Glycerol-3-phosphate acetyltransferase</i>	Chilling tolerance	Yokoi <i>et al.</i> (1998)
		<i>Heat shock protein 101</i>	Heat tolerance	Agarwal <i>et al.</i> (2003)
		Gibberellin insensitive	Dwarfism	Peng <i>et al.</i> (1999)
		H ⁺ /Ca ²⁺ antiporter	Seed calcium content	Kim <i>et al.</i> (2005a)
Animalia	<i>Phaseolus vulgaris</i>	Ferritin	Increase seed iron content	Lucca <i>et al.</i> (2001b)
	Wheat	DREB/CBF	Abiotic stress tolerance	Shen <i>et al.</i> (2003)
	Human	Cytochrome P450 mono oxygenase genes	Herbicide tolerance	Inui <i>et al.</i> (2001)
	Jellyfish	Lactoferrin	Iron binding supplement	Nandi <i>et al.</i> (2002)
		Lysozyme	Valuable industrial enzyme	Hennegan <i>et al.</i> (2005)
		Human granulocyte colony stimulating factor	Valuable industrial factor	Hong <i>et al.</i> (2006)
		Green fluorescent protein	Selecting/screening marker	Vain <i>et al.</i> (2003)

marker-free plants. All of the strategies mentioned have been reviewed and extensively referenced by Bajaj and Mohanty (2005) and Kathuria *et al.* (2007). A further advancement and simplification on the use of *cre/loxP* system was achieved by circumventing the need to express *cre* under spatiotemporal control. A fusion of the membrane translocation sequence from the Kaposi fibroblast growth factor (FGF-4) with CRE was used as cell permeable recombinase to deliver the latter into plant cells and effect marker excision (Cao *et al.*, 2006). An additional strategy to generate transgenic plants devoid of undesirable sequences such as the vector DNA sequences and marker genes is to biolistically co-transform plants with minimal cassettes of the marker gene and the gene of interest (Fu *et al.*, 2000a; Breitler *et al.*, 2002; Loc *et al.*, 2002; Agrawal *et al.*, 2005). This strategy led to higher frequency of single copy integration events as also a higher frequency of independent integration of the marker and the gene of interest, which can be analyzed for segregation in the next generation.

2.1.2 Agronomic trait enhancement

The desirable characteristics in any crop plant are a healthy life cycle leading to copious yields. In almost 20 years since the first transgenic rice plants were generated (Toriyama *et al.*, 1988; Zhang and Wu, 1988), the state of the art now allows facile examination and assessment of the role of heterologous and endogenous genes for agronomic trait improvement. For improvement of rice through transgenic approaches these traits translate into several agronomically desirable characters as detailed below.

2.1.2.1 Virus resistance

Viruses affecting rice crop include the RYMV, rice tungro bacilliform or spherical virus (RTBV/RTSV), rice stripe virus (RSV), rice ragged stunt virus (RRSV), RGSV, and RHBV. Transgenic approach to generate virus-resistant rice was first reported by Hayakawa *et al.* (1992) against RSV using the coat protein (CP)-mediated resistance. Other examples include CP against RHBV (Lentini *et al.*, 2003), RTSV (Sivamani *et al.*, 1999),

and RYMV (Kouassi *et al.*, 2006). Additional strategies used expression of ribozyme against dwarf virus (Han *et al.*, 2000), spike protein against RRSV (Shao *et al.*, 2003), and replicase against RTSV (Huet *et al.*, 1999). Silencing of the viral RNA dependent RNA polymerase was used to generate resistance to RYMV (Pinto *et al.*, 1999). Modification of host factors involved in virus replication against RTBV (Dai *et al.*, 2006) or even translation initiation factor 4G against RYMV (Albar *et al.*, 2006) has also been used. Partial to complete resistance to viral infection was demonstrated but no field studies have been carried out.

2.1.2.2 Bacterial resistance

Bacterial blight in rice is caused by *X. oryzae* pv. *oryzae* (*Xoo*). Resistance to bacterial blight is conferred to a limited extent by a 30-member family of rice endogenous genes called *Xa1* to *Xa29* (Xiang *et al.*, 2006). However, the expression patterns of these do not restrict the natural variation and evolution of resistance in the bacterial strains thus necessitating transgenic approaches using the endogenous genes with heterologous promoters for a powerful and enduring resistance response. Using *Xa21*, the most promising gene of the family (Song *et al.*, 1995) and *Xa26*, transgenic rice resistant to blight in field tests was created (Tu *et al.*, 1998; Sun *et al.*, 2004; Zhai *et al.*, 2004). Additionally, overexpression of endogenous transcription factor *OSWRKY71* implicated in defense signaling pathway was used to obtain resistance to blight (Liu *et al.*, 2006). Recently overexpression of the *OSWRKY13* led to resistance against bacterial blight and fungal blast with evidence for links through activation of salicylic acid (SA)-dependent and suppression of jasmonic acid (JA)-dependent signaling pathways (Qiu *et al.*, 2007). Other endogenous rice genes used against bacterial diseases are the *OSYK1* against bacterial stripe (Hayashi *et al.*, 2005), the *OSRAC1* (Ono *et al.*, 2001), and *OSRACB* (Jung *et al.*, 2006) against bacterial blight. Heterologous genes used against bacterial diseases in rice are the antibacterial peptide cecropin from *Bombyx mori* (Sharma *et al.*, 2000), the oat *ASTH1* gene (Iwai *et al.*, 2002), the sweet pepper ferredoxin gene (Tang *et al.*, 2001) and the *Arabidopsis*

NPR1 gene (Chern *et al.*, 2001, 2005). Yuan *et al.* (2007) confirmed that the rice *NPR1* is an ortholog of the *Arabidopsis NPR1* and its overexpression also confers resistance against bacterial blight and fungal blast perhaps through mediating antagonistic crosstalk between the SA- and the JA-dependent pathways was shown to confer resistance to bacterial blight.

2.1.2.3 Fungal resistance

M. grisea is the causal organism for rice blast and *R. solani* is the causal organism for rice sheath blight disease. Transgenic rice overexpressing the endogenous resistance genes (*R*, *Pi-ta*, *Nbs2-Pi9*, *Pid2*) against fungal blast under altered expression regimes was shown to confer resistance to *M. grisea* (Bryan *et al.*, 2000; Chen *et al.*, 2004; Qu *et al.*, 2006). Chitinase genes from rice or other fungi have been used to generate transgenic rice resistant against *Magnaporthe* and *Rhizoctonia* (Lin *et al.*, 1995; Datta *et al.*, 2001; Sridevi *et al.*, 2003). Pathogenesis-related protein *PR2* was used by Nishizawa *et al.* (2003) and a defense-related gene *RIR1b* was used by Schaffrath *et al.* (2000) for rice resistance against *Magnaporthe*. Wang *et al.* (2006) demonstrated that the thiamine biosynthesis gene *OSDR8* that acts in the signal transduction pathway could confer blast resistance, while Uchimiya *et al.* (2002) demonstrated the similar use of *OSKY1*, a maize *HMI* homolog. The *OSWRKY13* gene, which confers blight resistance, also confers blast resistance through the involvement of salicylate- and jasmonate-dependent signaling (Qiu *et al.*, 2007). The *B. mori* antibacterial peptides cecropins were also used as antifungal peptides (Coca *et al.*, 2006). Recently, Zhu *et al.* (2007) introduced four antifungal genes, two basic chitinases *RCH10* and *RAC22*, and the β -glucanase and *B-RIP* (ribosome inactivating protein) in super hybrid rice and demonstrated high resistance against not just blast but also against false smut and kernel smut caused by *Ustilaginoides virens* and *Tilletia barclayana*, respectively. Manipulating the endogenous levels of JA in transgenic rice through pathogen inducible regulation of allene oxide synthase—a key enzyme in JA biosynthesis—led to enhanced activation of pathogenesis related (PR) genes and blast resistance (Mei *et al.*, 2006).

Examples of glucanases, ribozyme inactivating proteins (RIPs), and other genes used to develop blast-resistant rice are illustrated in Kathuria *et al.* (2007).

2.1.2.4 Nematode resistance

The endogenous gene oryzacystatin was altered and used to generate transgenic rice (Vain *et al.*, 1998), which resulted in 55% reduction in egg production by *Meloidogyne incognita* or the root-knot nematode.

2.1.2.5 Insect resistance

The major insect pests affecting rice crop include *Nephotettix virescens* (green leafhopper), *N. lugens* (brown planthopper), *O. oryzae* (gall-midge) *S. incertulas* (yellow/white stem borer), *C. suppressalis* (striped stem borer). Insects act as primary pest and as vectors for viral infections of rice. Transgenic strategies using baculovirus through the insect's enhanced susceptibility by expressing the virus-enhancing factor (Hukuhara *et al.*, 1999) did not become popular due to the slow mode of action of the virus. Expressing protease inhibitors targeted against the insect proteases has been a popular strategy. Protease inhibitors such as the *SBTI*, *CPTI*, *PINII*, and *ITRI* have been used with limited success (Duan *et al.*, 1996; Xu *et al.*, 1996; Lee *et al.*, 1999; Alfonso-Rubi *et al.*, 2003). However, by far the most popular approach has been the use of *Bt* *Cry* genes. Since the first transgenic rice expressing the *cry1Ab* generated by Fujimoto *et al.* (1993), various rice varieties have been transformed with different *cry* proteins in their original, modified, or fully synthetic versions (extensively reviewed in Tyagi *et al.*, 1999; Khush and Brar, 2002; Bajaj and Mohanty, 2005; Kathuria *et al.*, 2007). Countering the capacity of target insects to develop concomitant resistance to *cry* proteins has been the subject of extensive research in deploying the transgenic *Bt* *cry* protein strategy, which holds promise due to its initial desirable effects on controlling the insect infestation and crop damage. Gene pyramiding of different *cry* proteins is seen as one viable strategy (Maqbool *et al.*, 2001;

Loc *et al.*, 2002; Bashir *et al.*, 2005). Fusion between cry proteins and carbohydrate-binding moieties of lectins is another strategy that was shown to increase the range of target insects (Mehlo *et al.*, 2005). Field tests of rice expressing cry proteins have shown limited success (Tu *et al.*, 2000; Ye *et al.*, 2001, 2003; Wu *et al.*, 2002; Bashir *et al.*, 2004; Breitler *et al.*, 2004). The fusion proteins, gene pyramiding not just with cry proteins but also with other insecticidal proteins, and agronomic deployment strategies as part of the integrated pest management has been suggested as the route to creating insect-resistant plants (Christou *et al.*, 2006; Ferry *et al.*, 2006). The cry proteins are not effective against the hemipteran insects. Plant lectins such as the galanthus nivalis agglutinin (GNA) have been shown to be effective against insects such as brown planthopper (BPH), green leafhopper (GLH), and white-backed planthopper (Rao *et al.*, 1998; Sudhakar *et al.*, 1998; Sun *et al.*, 2002; Nagadhara *et al.*, 2003, 2004). The *Allium sativum* leaf lectin was shown by Saha *et al.* (2006) to be effective against BPH and GLH. The GNA in combination with the cry proteins (Maqbool *et al.*, 2001; Ramesh *et al.*, 2004) or in combination with *SBTI* (Li *et al.*, 2005) extended the range of target insects to which the transgenic plants were tolerant. Yet other molecules such as the avidin (Yoza *et al.*, 2005) and the spider insecticidal protein (Qiu *et al.*, 2001) have been tested in transgenic rice.

2.1.2.6 Drought, salt, submergence, and temperature stress tolerance

Although rice is a sturdy grass crop that grows in varied climates and weather conditions, the gap in yield potential and yield harvest as affected by abiotic stresses cannot be afforded under the present demand regimes. However, transgenic approaches to address a particular stress often favorably impact the other due to amelioration of a common stress response pathway. One approach that simultaneously affects favorably more than one abiotic stress is overproduction of cell solutes such as glycine betaine, trehalose, proline, polyamines and late embryogenesis abundant proteins. The genes used to achieve solute overproduction in transgenic rice are reviewed in Kathuria *et al.* (2007). A recent example of using osmolyte accumulation

against salt and drought tolerance is the overproduction of mannitol in rice using the *Escherichia coli* mannitol-1-phosphodehydrogenase (Pujni *et al.*, 2007). Ion channel and water channel proteins that facilitate modification of the cell's and the vacuole's osmotic balance have been used to develop drought-tolerant rice. For example, overexpression of the aquaporin *RWC3* from rice (Lian *et al.*, 2004) and that of the Na^+/H^+ antiporter from rice, *Suaeda salsa*, *Artiplex* or *E. coli* (Ohta *et al.*, 2002; Fukuda *et al.*, 2004; Zhao *et al.*, 2006) increased salinity tolerance in transgenic rice. The usefulness of the strategy to increase salt tolerance in transgenic rice through a rice Na^+/H^+ antiporter gene (*OSNHX1*) was reinforced recently by Chen *et al.* (2007). Production of free radicals and reactive oxygen species mostly accompanies different abiotic stresses (Mittler *et al.*, 2004) and the common signaling pathways for the perception and response to oxidative stress indicate that strategies targeting oxidative stress may ameliorate multiple stresses. The presence of oxidative stress response *cis* elements in abiotic stress response genes such as *OSISAP1* (Mukhopadhyay *et al.*, 2004; Tsukamoto *et al.*, 2005) supports this strategy. Hoshida *et al.* (2000) obtained salt-tolerant transgenic rice by overexpressing glutathione synthase, a reactive oxygen species metabolism enzyme. Similarly, constitutive overproduction of pea superoxide dismutase (Wang *et al.*, 2005) and protoporphyrinogen oxidase (Jung and Back, 2005) led to salt-tolerant rice. An additional common reaction to stress is the Ca^{2+} -mediated signaling to activate response pathways (Knight and Knight, 2001). Proteins involved in Ca^{2+} -mediated signaling such as calcineurin A (Ma *et al.*, 2005), calcium-dependent protein kinases (*OSCDPK7*; Saijo *et al.*, 2000), and MAP kinases (*OSMAPK5*; Xiong and Yang, 2003) were shown to generate salt-, drought-, and cold-tolerant rice.

Recently the *DREB/CBF* regulatory genes have also been shown to be common to cold, dehydration, and salt stress (Dubouzet *et al.*, 2003). Overexpressing endogenous and heterologous (wheat and *Arabidopsis*) *DREB/CBF* class of genes in rice has led to a better understanding of the signaling pathways and generated multiple-stress-tolerant rice (Oh *et al.*, 2005). Overexpression of other regulatory genes such as the transcription factor *SNAC1* has also

been shown to generate drought- and salt-tolerant rice (Hu *et al.*, 2006).

As opposed to salt and drought tolerance, submergence tolerance is important in certain areas. Quimio *et al.* (2000) generated the first rice transgenics exhibiting submergence tolerance by overexpressing the *pyruvate decarboxylase* gene (*PDC1*). Xu *et al.* (2006) demonstrated submergence tolerance in transgenic rice by expressing an ethylene responsive-factor-like gene (*SUB1A*), which affects the expression levels of other genes of the same family (*SUB1C*) and the *alcohol dehydrogenase* (*ADH1*) gene expression.

Temperature stress tolerance has been engineered through the use of heat shock proteins for high temperature from rice itself (SPL7; Yamanouchi *et al.*, 2002) or from *Arabidopsis* (HSP101; Agarwal *et al.*, 2003; SHSP17.7; Murakami *et al.*, 2004). Low-temperature stress tolerance was engineered through overexpression of genes affecting the level of unsaturation of the fatty acids in the chloroplast phosphatidylglycerol (Ariizumi *et al.*, 2002; Takesawa *et al.*, 2002).

2.1.2.7 Mineral stress tolerance

Plant stress associated with excess or lack of mineral nutrients can adversely affect yields to a large degree. Soil pH dictates the availability of nutrients such as iron, phosphorus, aluminum, etc. High pH soils limit the availability of iron, which was ameliorated by overexpressing nicotianamine synthase, because it is functional in the biosynthetic pathway of iron chelating phytosiderophores. Barley phytosiderophore synthesizing genes (*NAAT-A* and *NAAT-B*) were also used to show enhanced survival in high pH, low iron availability soils (Takahashi *et al.*, 2001). Phosphate starvation in pH imbalanced soils was relieved through the expression of a rice transcription factor *OSPTF1* (Yi *et al.*, 2005). Begum *et al.* (2005) demonstrated that transgenic rice expressing the maize *PEPC* led to exudation of oxalate thus enhancing the plant's capacity to adapt to high pH, low phosphorus soil conditions. Alternately, low pH soils pose the problem of toxic aluminum ions that inhibit root elongation. Aluminum ion complexing organic acids such as citrate and malate led to transforming rice with a

wheat malate transporter (*ALMT-1*; Sasaki *et al.*, 2002) to generate aluminum-resistant plants but the approach was not very successful.

2.1.2.8 Herbicide tolerance

The trait of herbicide tolerance was one of the first to be introduced in rice, tested in the fields, and used commercially. Transgenic rice has been developed expressing the herbicide tolerance gene *bar* from streptomyces (Christou *et al.*, 1991; Datta *et al.*, 1992), Cytochrome P450 monooxygenases from humans (Inui *et al.*, 2001; Kawahigashi *et al.*, 2005, 2006) or pigs (Kawahigashi *et al.*, 2005) and the rice glutathione S-transferases (Deng *et al.*, 2003). Tolerance to a number of herbicides was demonstrated through these studies. Lee *et al.* (2000) and Jung and Back (2005) also generated herbicide tolerance in rice through expressing the *Bacillus subtilis* *protax* gene.

2.1.2.9 Increased grain yield

With the increasing population, increasing crop yield through contribution of the transgenic technologies in the breeding programs is almost a prerequisite now. Although addressing biotic and abiotic stress resistance is an indirect route to yield increase, a more direct route is to increase grain number, size, and weight. Enhanced activity of adenosine diphosphate-glucose pyrophosphorylase led to increase in seed weight per plant (Smidansky *et al.*, 2003). Manipulating complex traits such as light signal transduction and photosynthetic efficiencies through efforts to convert the rice C₃ plant into C₄ plant is also underway. Kong *et al.* (2004) demonstrated an increase in seed yield in transgenic rice expressing the *Arabidopsis* phytochrome A gene. Plant hormones influence grain yield. Sakamoto *et al.* (2003) overexpressed the gibberellin 2-oxidase, generating a semidwarf, high-yielding transgenic after a connection was established between dwarfism and gibberellin response (Peng *et al.*, 1999; Sasaki *et al.*, 2002). Lack of C-22 hydrolase, a brassinosteroid biosynthetic enzyme leads to erect leaves and increased grain yield (Sakamoto *et al.*, 2006). Transgenic rice expressing

the brassinosteroid receptor gene *OSBRI* and exhibiting brassinosteroid insensitivity showed similar changes in morphology and increased yield (Morinaka *et al.*, 2006). Similarly, expressing the defective allele of *OSCKX2*—a cytokinin oxidase/dehydrogenase showed enhanced cytokinin and increased grain yield (Ashikari *et al.*, 2005). Flower development is directly related to grain yield capacities. Manipulation of the transgenic expression of different rice MADS box transcription factors was shown to affect flower morphology indicating genes necessary for normal flower development (Prasad *et al.*, 2001, 2005; Kyoizuka and Shimamoto, 2002; Sentoku *et al.*, 2005; Chen *et al.*, 2006a; Yamaguchi *et al.*, 2006). These studies helped to map the rice flower development on the known ABC model of *Arabidopsis* flower development. Genes other than the MADS box transcription factors that affect the flower morphology have also been elucidated (Jang *et al.*, 2003, 2004). Other rice genes studied through transgenic rice for their role in flowering time, shoot-to-flower transition time, panicle number, and density and other growth and development patterns have been reviewed in Kathuria *et al.* (2007) including the genes concerned with phytohormone biosynthesis mentioned above and the additional ethylene biosynthesis and response genes that affect plant morphology (Mao *et al.*, 2006). Regulatory genes apart from the transcription factors, such as those concerned with giving rise to further regulatory moieties of micro-RNA also provide an insight into plant architecture (Liu *et al.*, 2005). Flower development and viability also feeds into the important aspect of generating hybrid rice through male sterility. Generating cytoplasmic or genic male sterility or restoration of the same has been demonstrated through transgenic approaches (Komori *et al.*, 2004; Wang *et al.*, 2006). These studies help in understanding factors that can be used to develop an optimal plant architecture and life cycle that further helps increase grain yields. Interestingly, roots that sustain the entire plant and whose normal growth and development dictates that genetic growth patterns of the aerial parts are adhered to through supply of water and nutrients, have not been investigated to the same extent as perhaps shoot branching patterns and flower development. Recently, transgenic studies

have elaborated the role of some rice genes in root development showing relationships to auxin levels (Ge *et al.*, 2004; Nakamura *et al.*, 2006).

2.1.2.10 Nutritionally enhanced seeds

Since rice is the staple food of a large population in economically underdeveloped, and developing countries, which cannot afford expensive fruits and vegetables, enhancement of the nutritional quality of the rice seeds can directly contribute to the health of this population. The first target in this regard was increasing the content of carotenoids to result in enhancement of vitamin A in the seeds. Over the last decade, rice has been engineered with carotenoid biosynthesis genes from rice, maize, daffodil, and bacteria sequentially improving the expression levels by approaches such as codon optimization and tissue-specific expression (Burkhardt *et al.*, 1997; Ye *et al.*, 2000; Datta *et al.*, 2003, 2006 Hoa *et al.*, 2003; Paine *et al.*, 2005). The second target is to improve the rice seeds for essential amino acid content. To increase the content of tryptophan the biosynthetic enzyme anthranilate synthase gene was used (Morino *et al.*, 2005; Wakasa *et al.*, 2006). Similarly, the seed methionine and cysteine content has been improved by expressing the sesame albumin protein (Lee *et al.*, 2003). Increasing the levels of polyunsaturated fatty acid α -linolenic acid in rice bran has also been achieved (Anai *et al.*, 2003). Seed iron content was increased by transforming rice with human lactoferrin gene (Nandi *et al.*, 2002), the *Phaseolus vulgaris* ferritin gene (Lucca *et al.*, 2001a), the soybean ferritin gene (Goto *et al.*, 1999; Vasconcelos *et al.*, 2003) or the *Aspergillus fumigatus* phytase gene (Lucca *et al.*, 2001a). In another breakthrough, the seed calcium content was manipulated to lower the incidence of osteoporosis, an incidental problem occurring through rice consumption amongst the economically poorer communities. A H^+/Ca^+ transporter gene was integrated to achieve higher calcium content (Kim *et al.*, 2005a). However, any nutritional improvement of rice seed can most easily be affected by changes in starch content. Overexpression of one allele of the starch synthase gene resulted in the increase of seed starch (Hirano *et al.*, 1998). A change in the amylose to

amylopectin ratio of the rice seed was targeted by transforming rice either with isoamylase 1 silencing construct or with the *E. coli* glycogen-branching enzyme (Fujita *et al.*, 2003; Kim *et al.*, 2005b) to change the physiological properties of starch. A postharvest value-added modification for the use of rice starch was engineered by introducing the wheat puroindoline genes *PINA* and *PINB* that rendered the grains much softer than the control. The “Soft-Rice” has numerous applications in the food industry.

2.1.2.11 Variation in transgene constructs

Most transgenic plants are primarily developed using strong constitutive promoters. For rice, the most commonly used promoters are the CaMV 35S, rice *ACT1* and the maize *UBI1*. The CaMV 35S promoter was shown to contain a recombination hotspot (Kohli *et al.*, 1999a), readily leading to transgene rearrangements. Other viral promoters have been used in rice such as the one from cestrum yellow leaf curling virus (CYLF) (Stavolone *et al.*, 2003) and milk vetch dwarf virus (MVDV) (Shirasawa-Seo *et al.*, 2005). Among the nonviral constitutive promoters that have been used, the rice cytochrome c gene promoter was highly active in different parts of the plant including the embryo and the calli (Jang *et al.*, 2002). Using introns further enhanced expression of the constitutive promoters. Tanaka *et al.* (1990) used the first intron of castor bean catalase to enhance *gus* expression driven by the CaMV 35S promoter in rice. The maize *ADH1* first intron became quite popular in plant transformation constructs and was first used in rice by Kyoizuka *et al.* (1991). Simultaneously, McElroy *et al.* (1991) used the first intron of the *ACT1* gene in combination with the *ACT1* promoter. However, the most popular intron was the first intron of the maize *UBI1* gene in combination with the *UBI1* gene promoter itself (Toki *et al.*, 1992; Cornejo *et al.*, 1993). The *ADH1* intron 1 was, however, used downstream of the CaMV 35S promoter (Taylor *et al.*, 1993). Other DNA sequences tested for their functionality in regulating the level of expression of a transgene were the matrix attachment region (MAR) sequences (Vain *et al.*, 2002). Xue *et al.*

(2005) used the tobacco TM2 MARs to enhance expression from both constitutive and inducible promoters. Novel regulatory sequences such as the *REB* activator fused to the *GLB* promoter increased the transgene activity (Yang *et al.*, 2001) while the *SRS* element fused to the *ACT* promoter also achieved enhanced expression levels (Lu *et al.*, 1998). Nguyen *et al.* (2004) increased constitutive expression up to fivefold, by using the T7RNA polymerase-directed expression system in rice. However, constitutive promoters are not always desirable since transgene expression levels may need to be spatiotemporally controlled and coordinated. This can be achieved either through tissue/stage-specific or inducible promoters *per se* (Ito *et al.*, 2006) or through coupling regulatory, inducible/responsive *cis* elements to workhorse constitutive promoters (Su *et al.*, 1998). Further examples of both categories have been extensively reviewed in Bajaj and Mohanty (2005) and Kathuria *et al.* (2007). Promoters from diverse sources have been tested in rice suggesting its suitability for heterologous functional analysis or complementation of promoter elements of other organisms (Kathuria *et al.*, 2007).

2.2 Methods of Genetic Transformation

2.2.1 Protoplast technology

The first transgenic rice plants were obtained with rice protoplasts using electroporation (Toriyama *et al.*, 1988) and polyethylene glycol (PEG)-mediated methods (Zhang and Wu, 1988). Dividing rice protoplasts from which fertile plants can be regenerated are usually generated from embryogenic cell cultures normally derived from immature embryos (Vasil, 1988). Toriyama *et al.* (1988) used protoplasts isolated from anther-derived cell suspension cultures of *O. sativa* L. cv. Yamahoushi to electroporate two plasmids containing CaMV 35S promoter-driven aminoglycoside phosphotransferase II and β -glucuronidase genes. Shimamoto *et al.* (1989) were the first to recover fertile transgenic *Japonica* rice using the electroporation method. Datta *et al.* (1990) were the first to recover fertile transgenic *Indica* rice (*O. sativa* var. Chinsurah Boro II) from protoplasts derived from immature

pollen grains (microspores) with a hygromycin phosphotransferase (*hph*) gene under control of the CaMV 35S promoter using the PEG-mediated technique.

Protoplast-mediated transformation has many limitations. These include difficulties in regeneration of elite *Japonica* and *Indica* varieties (Ayres and Park, 1994), the production of sterile and phenotypically abnormal regenerated plants (Datta *et al.*, 1992), the integration of multiple copies of genes into genomes (Tada *et al.*, 1990), combined with the fragmentation and rearrangement of transgenes (Xu *et al.*, 1995) and their occasional non-Mendelian inheritance (Peng *et al.*, 1995).

2.2.2 Particle bombardment

Continuous and directed research efforts to use *Agrobacterium*-mediated transformation for cereals have recently made the technology routine in many laboratories around the world. However, earlier difficulties in transforming cereals with *Agrobacterium* led to a search for alternative strategies. Wang *et al.* (1998) first used the biolistics technology of bombarding DNA-coated gold particles accelerated under vacuum to achieve transient expression of transgenes in rice. Christou *et al.* (1991) reported the first stable transformation using a modification of the same technology whereby the particles were accelerated by an electric arc. This method of transformation became the method of choice for nearly a decade since it is genotype independent and less labor intensive. A number of genes were introduced in rice using the biolistics technology (reviewed in Giri and Laxmi, 2000; Bajaj and Mohanty, 2005; Kathuria *et al.*, 2007). An *Indica* rice population was created with *Ac/Ds* transposon for saturation mutagenesis and functional genomics using the biolistics method (Kohli *et al.*, 2001). Initial observations of transgene rearrangements and multicopy insertion events in transgenic rice lines (Kohli *et al.*, 1998, 1999a) were ascribed as reasons for transgene silencing (Kumapatla and Hall, 1998a, b; Dai *et al.*, 2001b). Transgene rearrangements were indeed shown to be responsible for lack of transgene expression but integration of multicopy transgenes does not always lead to silencing

(Gahakwa *et al.*, 2000; Kohli *et al.*, 1999b). In fact, fragmentation and rearrangement of transgene(s) were shown to be responsible for silencing (Yang *et al.*, 2005), especially when multiple copies are present. However, reducing the chances of rearrangements by removing the vector backbone sequences from the transforming constructs led to independent integration of intact multicopies, which exhibited high and stable expression patterns (Fu *et al.*, 2000a; Agrawal *et al.*, 2005). This approach also allayed the concerns on antibiotic selectable marker and other vector backbone sequence integration in the transgenic plants. This approach of “clean DNA” transformation using the biolistics method is gaining popularity for transformation of rice (Breitler *et al.*, 2002; Loc *et al.*, 2002), other cereals such as wheat (Yao *et al.*, 2006), and yet other plants such as potato (Romano *et al.*, 2003) and grapevine (Vidal *et al.*, 2006).

2.2.3 *Agrobacterium*-mediated transformation

Agrobacterium tumefaciens is a phytopathogenic soil bacterium, sometimes named as a “natural genetic engineer” due to its ability to transform plant cells with a part of its tumor-inducing plasmid (Ti plasmid) known as the T-DNA segment (Chilton, 2001). Wounding of plants allows entry of bacteria and provides phenolic compounds that activate the DNA transfer machinery of *A. tumefaciens* in which a series of molecular events results in transfer of T-DNA from the bacterial cell to a plant cell and subsequently into the plant genome (Gelvin, 2000, 2003; Zhu *et al.*, 2000; Zupan *et al.*, 2000). Diverse arrays of sophisticated plant transformation vectors have been derived to exploit this naturally occurring gene transfer mechanism in the genetic engineering of plants (Bevan, 1984; Tzifira and Citovsky, 2006). This mode of gene delivery is both convenient and efficient. Among its list of major advantages is the transfer of a small number of intact DNA fragments (Hamilton *et al.*, 1996; Dai *et al.*, 2001b) that exhibit a normal Mendelian gene transmission to progeny (Budar *et al.*, 1986).

2.2.3.1 Transformation of dicots

The earliest reports of successful *Agrobacterium*-mediated transformation were for several dicotyledonous plants. Murai *et al.* (1983) demonstrated that a part of a bean phaseolin seed protein gene was transcribed in transformed sunflower cells. Horsch *et al.* (1985) combined gene transfer, plant regeneration, and an effective kanamycin-based selection for transformants to generate transgenic petunia, tobacco, and tomato by means of a novel leaf disk transformation-regeneration method. Subsequently, *Agrobacterium*-mediated transformation was extended to other dicots such as soybean (Hinchey *et al.*, 1988) and walnut (McGranahan *et al.*, 1988) culminating in the *in planta* *Agrobacterium*-mediated gene transfer by infiltration of adult *Arabidopsis thaliana* plants (Bechtold *et al.*, 1993).

2.2.3.2 Transformation of monocots

De Cleene and De Ley (1976) showed that members of the Liliales and Arales are susceptible to *Agrobacterium*, and early reports exist for *Agrobacterium*-mediated transformation of both *Asparagus officinalis* (Hernalsteens *et al.*, 1984) and *Dioscorea bulbifera* (Schafer *et al.*, 1987). Grimsley *et al.* (1986, 1987) demonstrated transfer of T-DNA in maize seedlings infected with *A. tumefaciens* containing the maize streak virus (MSV) in the T-DNA (a process known as agroinfection). Nevertheless, monocots, especially the cereals were generally considered outside the host range of *A. tumefaciens* (Potrykus, 1990; Smith and Hood, 1995). As a consequence, protoplast electroporation and particle bombardment techniques were extensively used for transformation of cereals until Hiei *et al.* (1994) provided rigorous evidence for the production of many fertile rice plants using a well-defined *Agrobacterium*-mediated transformation procedure.

This built upon the first successful demonstration of *Agrobacterium*-mediated transformation of rice by Raineri *et al.* (1990) who used mature embryos from wounded germinated seeds of *Japonica* cultivars Nipponbare and Fujisaka5 to deliver *Agrobacterium* strain LBA4404 with *nos-nptII* and CaMV 35S-*gus*. They obtained kanamycin-resistant calli, and showed T-DNA

integration by Southern analysis, but failed to regenerate transgenic plants.

Chan *et al.* (1992) obtained G418-resistant calli from root explants of the *Indica* variety Taichung native I and showed T-DNA integration by Southern analysis. Later (Chan *et al.*, 1993) successfully regenerated four transgenic rice plants, only one of which produced progeny. To achieve successful infection, they added extracts from a potato suspension culture to the co-cultivation medium, as these are rich in phenolic compounds that aid in susceptibility to *Agrobacterium*.

In the landmark paper of Hiei *et al.* (1994), *Agrobacterium* strains LBA 4404 and EHA101 harboring pTOK233, a “superbinary” vector, were employed. In these strains, the plasmid containing the T-DNA bears a fragment of the S-Vir region that includes additional *virB* and *virG* genes derived from pTiBo542. Transgenic plants were successfully obtained for *Japonica* varieties Tsukinohikari, Asanohikari, and Koshihikari. T-DNA regions in the transformed plants were detected by Southern analysis; their boundaries sequenced, and Mendelian transmission of transgenes to the R₂ generation was demonstrated. This achievement was followed by the first reports of transgenic *Indica* rice plants, namely, Basmati 370 and Basmati 385 (Rashid *et al.*, 1996), and of *Javanica* rice, Gulfmont and Jefferson (Dong *et al.*, 1996). All these studies used calli derived from scutellar tissue, and included acetosyringone, a phenolic compound, in the co-cultivation media. Dong *et al.* (1996) also conducted sequence analysis of right border fragments of one of their transgenic lines, confirming that insertion was into a coding region of rice nuclear DNA. This analysis also revealed the presence of relatively short regions of permuted T-DNA border sequences, similar to those found after *Agrobacterium*-mediated transformation of dicots. Figure 2 details the production of fertile transgenic rice plants by *Agrobacterium*-mediated transformation of scutellum-derived calli.

Broadening the range of tissues competent for *Agrobacterium*-mediated transformation was another significant step in rice biotechnology. Immature embryos from both *Japonica* (Radon) and *Indica* (TCS10 and IR72) varieties (Aldemita and Hodges, 1996) and isolated shoot apices from tropical *Japonica* (Maybelle) varieties (Park *et al.*,

Figure 2 Production of fertile transgenic rice plants by *Agrobacterium*-mediated transformation of scutellum-derived calli. (1) Calli on selection medium (50 mg l^{-1} hygromycin); (2, 3, 4) GUS expression on different hygromycin-resistant calli; (5) plantlets after 3–4 weeks on regeneration medium; (6) fertile plant; (7) detail of panicle

1996) were used successfully. Dong *et al.* (2001) used inflorescence explants from the *Japonica* variety Taipei 309 and regenerated transgenic rice plants at frequencies as high as 80% from inflorescences when the individual floral organs were 1–2 mm long. This provided a simpler and more rapid alternative to the scutellar-based approach, by minimizing the tissue culture steps and reducing somaclonal variation, and also enhanced the potential for transformation of genotypes recalcitrant to tissue culture and regeneration. Another *in planta* method by Supartana *et al.* (2005) employed 2 days' presoaked seeds of *Japonica* variety Koshihikari to obtain transgenic plants by piercing a site of the husk overlying the embryonic apical meristem with a needle that had been dipped in an *Agrobacterium* inoculum. The inoculated seeds were then grown to maturity and allowed to pollinate naturally to set seeds. Transformation efficiency was estimated to be 40% by polymerase chain reaction (PCR) and 43% by β -glucuronidase histochemical assay. In other high-throughput methods, Terada *et al.* (2004) employed seed-derived calli to obtain 1000 stable transformants from as few as 150 explants in *Japonica* rice; Toki *et al.* (2006) successfully regenerated transgenic rice plants within a month (as opposed to the standard three months in all related techniques), from scutella of 1-day precultured mature seeds, thus reducing the risk

of somaclonal variation attributable to prolonged tissue culture.

A more recent method of efficient *Agrobacterium*-mediated transformation in rice used microspore-derived haploid callus cells (Y. Jiang and T.C. Hall, personal communication). Compared to methods using diploid cells or tissues as starting materials for *Agrobacterium*-mediated transformation, rice transformation of haploid cells such as microspore-derived callus has several advantages. Chromosome doubling of a transgenic haploid cell produces DH transgenic homozygous cells that provide a method for rapid genetic fixation of the gene of interest that is transferred. Homozygous plants are valuable for plant breeding because almost all of the final products or cultivars released from plant breeding are homozygous. Traditional methods to obtain homozygous breeding lines following hybridization or mutagenesis often require years to succeed. Another advantage of haploids for genetic analysis is that dominance and recessivity are less likely to obscure gene expression, and the phenotype is a direct manifestation of the genotype since there is only one chromosome set in the haploid. Although *Agrobacterium*-mediated transformation of microspore-derived embryos was reported some time ago for *Datura innoxia* and *Nicotiana tabacum* (Sangwan *et al.*, 1993), limited success for rice was reported only

recently (Chen *et al.*, 2006a, b). The protocol for transgenic rice extends the methods for a highly efficient production of transgenic haploids and DH procedure using microspore-derived haploid callus as a target for *Agrobacterium*-mediated transformation.

2.2.4 Miscellaneous methods

Reports of several novel methods for successful transformation exist in the literature. Luo and Wu (1989) described a method to transform rice through a pollen tube pathway method. Guo *et al.* (1995) reported an effective system for introducing exogenous DNA into cells of embryonic calli of *Japonica* rice by first dehydrating the cells in a hypertonic buffer, then placing the cells in a medium of less negative osmotic potential containing the exogenous DNA, and employing a laser beam to puncture holes in cell wall and membrane to enable uptake of DNA expressing the fluorescent calcein. Yoo and Jung (1995) reported the uptake of *gusA* and *hpt* genes by imbibition of dry and viable rice embryos from a DNA solution. Matsushita *et al.* (1999) used scutellar tissues of rice embryos obtained from mature seeds and vortexed them in liquid medium containing plasmid DNA and silicon carbide whiskers to obtain transgenic plants expressing *gusA* and bialaphos resistance.

2.3 Selection Methods for Transgenic Plants

There are numerous critical factors that are of paramount importance in obtaining transgenic rice plants, and the relative efficiency, economy, experimental time, and reproducibility must be taken into consideration to adopt a particular technology whether it is particle bombardment or *Agrobacterium*-mediated transformation. The ultimate aim is to select an easy, efficient, and inexpensive method suited to the introduction of a single gene or multiple genes or a study, which requires functional genomics to identify the function of numerous genes in a high-throughput fashion.

2.3.1 Bacterial strains and vectors

Successful *Agrobacterium*-mediated rice transformation procedures are mostly based on the use

of supervirulent strains and superbinary vectors carrying the virulence region of pTiBo542 (Hood *et al.*, 1986; Komari *et al.*, 1986). Strain A281 (Hood *et al.*, 1987; Komari, 1989) with a wide host range and higher transformation efficiency was used by both Raineri *et al.* (1990) and Chan *et al.* (1993). The strain EHA101 (Hood *et al.*, 1986) was developed with two vector versions, one harboring a “disarmed” version of pTiBo542 and another with the “superbinary” vector, where a DNA fragment with the *virB*, *C*, and *G* genes was introduced into a small T-DNA-carrying plasmid that is used in a binary vector system (Komari, 1990). Hiei *et al.* (1994) tested the efficacy of both the supervirulent EHA101 and another ordinary strain LBA4404 in combination with pIG121Hm, a derivative of a “normal” binary vector pBIN19 (Bevan, 1984), and pTOK233, a derivative of “superbinary” vector pTOK162 (Komari, 1990). The LBA4404 (pTOK233) combination was slightly more effective than LBA4404 (pIG121Hm) and EHA101 (pIG121Hm), while EHA101 (pTOK233) alone was not very effective. Dong *et al.* (1996) demonstrated that LBA4404 (pTOK233) was most effective in *Javanica* rice. In general, an “ordinary” vector/strain combination proved effective in transforming cultivars that are easy to grow in tissue culture, and in case of cultivars difficult or recalcitrant to tissue culture, the choice of vectors and strains is more crucial. More recently, Jeon *et al.* (2000) showed that a combination of LBA4404 with common binary vectors resulted in callus transformation efficiencies of up to 40% from which transgenic plants were regenerated at a frequency of 85%.

2.3.2 Induction of *vir* genes

Agrobacterium was found to be attracted to wounded plant cells in response to several phenolic signal compounds, including 4-acetyl-2, 6-dimethoxy phenol (commonly known as acetosyringone) and 4-(2-hydroxy acetyl)-2,6-dimethoxy phenol (α -hydroxy acetosyringone) that activate the *vir* genes on Ti plasmids (Stachel *et al.*, 1985). Seven phenolic compounds were found to induce the expression of *vir* genes (Bolton *et al.*, 1986) but monocots appear not to produce, or produce at insufficient levels, these compounds to act as signals (Smith and Hood, 1995). Rice cells

may be capable of producing sufficient levels of inducing agent, as the first report of transgenic calli (Raineri *et al.*, 1990), did not require any phenolic compound addition in the co-cultivation media. The transfer of T-DNA is enhanced at an early stage of co-cultivation, and the efficiency of gene transfer is also increased when both the bacteria and the tissues are pretreated with acetosyringone (Aldemita and Hodges, 1996). Certain other factors, such as an acidic pH (Turk *et al.*, 1991), culture temperatures below 28 °C (Alt-Moerbe *et al.*, 1988), high osmotic pressure (Usami *et al.*, 1988), the presence of opines (Veluthambi *et al.*, 1989), and aldoses like D-glucose (Cangelosi *et al.*, 1990) also increase *vir* gene induction.

2.3.3 Tissues amenable to transformation

Binns and Thomashaw (1988) pointed out a distinct correlation between cell wounding and competency of such cells for transformation, and proposed that processes related to DNA synthesis and cell division are critical for the integration of delivered DNA into the host genome. The wound responses of monocots differ significantly from those of dicots, with the cells at the wound sites of monocots becoming lignified or sclerified with no apparent cell division (Kahl, 1982). This renders the choice of dicot explants such as leaf discs and hypocotyls useless *vis-à-vis* their monocot counterparts; hence, actively growing tissues need to be supplemented with *vir*-inducing compounds to ensure successful transformation. For generating transgenic rice, the favored choice has been mature or immature embryo (scutellum)-derived callus cultures (Hiei *et al.*, 1994; Dong *et al.*, 1996; Rashid *et al.*, 1996; Toki, 1997). Shoot apices (Park *et al.*, 1996) and immature embryos (Aldemita and Hodges, 1996) have also been employed with limited success.

The choice of tissue for transformation is also dependent on the rice genotype. *Japonica* and *Javanica* varieties are usually highly responsive to tissue culture and actively dividing callus cultures are the tissues of choice for these varieties (Hiei *et al.*, 1994; Dong *et al.*, 1996). A majority of *Indica* varieties falling under a different group, designated group I based on isozyme analysis (Glaszmann, 1987) are recalcitrant to tissue culture and transformation procedures. Aldemita

and Hodges (1996) used immature embryos to achieve transformation of two group I *Indica* cultivars, namely TSC10 and IR72, a method extended by Hiei *et al.* (1997) to many other group I varieties.

2.3.4 Co-cultivation and culture media conditions

The composition and incubation conditions of the co-cultivation and subsequent callusing media during the transformation process play a critical role in the initial transient transformation efficiencies and subsequent stable transgene integration. A modified N6 medium with B5 vitamins, 2,4-dichlorophenoxy acetic acid (2,4-D) supplemented with acetosyringone during co-cultivation was the medium of choice for both *Japonica* and *Indica* varieties (Hiei *et al.*, 1994; Rashid *et al.*, 1996; Toki, 1997), while MS-based media was used for *Javanica* varieties (Dong *et al.*, 1996). Media solidified with a gelling agent was preferred over liquid media, where β -glucuronidase (GUS) expression was low (Hiei *et al.*, 1997). The optimization of media (e.g., choice of N6 over MS) can be monitored based on transient expression of reporter genes like *gus*, as conditions allowing for a high level of transient expression are generally associated with a high frequency of stably transformed calli and subsequent transgenic plants (Hiei *et al.*, 1997). The *gusA* gene containing an intron in the coding region has been a very useful reporter as the GUS expression is limited to plant cells (Ohta *et al.*, 1990; Vancanneyt *et al.*, 1990).

2.3.5 Reporter genes and selectable marker genes

The most commonly used reporter gene in rice transformation was initially the β -glucuronidase gene (*gusA*) (Jefferson *et al.*, 1987), which served as a valuable tool to monitor transient expression early after transformation, providing an indication of the expected frequency of stable transgenic lines. Histochemical GUS activity was primarily localized at or around the vascular tissue in leaf, root, and flower organs and was also detected in the embryo and endosperm of dormant and germinating seeds (Terada and Shimamoto, 1990). Battra and Hall (1990) also observed GUS

activity in transgenic rice in the leaf epidermis, mesophyll, vascular bundles, in the cortex and vascular cylinder of the root, and marginal activity in the root epidermis. Fluorometric assay of various organs showed that GUS activity in transgenic rice plants was comparable to that seen in transgenic tobacco plants. A more recent innovation in the GUS reporter system involves the development of GUS *plus*TM (CAMBIA), which is a new reporter gene isolated from *Staphylococcus* sp. with superior properties to *E. coli gusA*. A version with the rice glycine-rich protein signal peptide for extracellular secretion providing rapid, *in vivo* GUS assays has been tested extensively in transgenic rice, and the gene has been codon optimized for high expression in plants. Vickers *et al.* (2003) developed a synthetic, codon-optimized xylanase gene (*sXynA*) as a reporter gene in conjunction with GUS *plus* for quantitative transient analyses in plants, which allows for sensitive assays at the low levels of transgene protein found in transiently transformed tissue extracts. The xylanase protein is stable, activity kinetics is linear over long time periods, and assays are cost effective. Kirby and Kavanagh (2002) developed a synthetic reporter gene called *NAN*, a codon-optimized derivative of *nanH*, a *Clostridium perfringens* gene, which encodes the so-called “small” cytoplasmic sialidase. This reporter system is aimed at providing a compatible and functionally equivalent reporter gene to *gusA*, which would facilitate dual promoter studies and internal standardization of expression analyses in the same transgenic plant.

In recent transgenic studies, the favorite reporter gene encodes the green fluorescent protein (GFP) from the jellyfish *Aequorea victoria* (Chalfie *et al.*, 1994). The lack of requirement for an exogenous substrate, cofactors or histochemical fixation makes GFP a particularly valuable reporter for plant cells. Several modifications of the native GFP have improved its thermotolerance and fluorescence, especially in plants (Siemering *et al.*, 1996; Haseloff *et al.*, 1997). For these reasons, GFP and its variants are widely used as attractive alternatives to *gusA* for assessment of promoter function and in optimizing plant transformation (Stewart, 2001). However, in leaves of transgenic rice, a dramatic decrease of GFP fluorescence was observed as the leaves aged. This was found to be associated with increases in chlorophyll

concentration (Zhou *et al.*, 2005) that, if not appreciated could lead to underestimating GFP expression levels. The removal of chlorophyll by etiolation or extraction with ethanol substantially restored GFP fluorescence in transgenic rice seedlings.

Selection marker genes are employed to select transformed tissues in culture media owing to their ability to confer resistance to chemical components added to the tissue culture media. Early rice transformation studies used the neomycin phosphotransferase (*nptII* or *aph(3')II* or *neo*) as a selection marker, that conferred resistance to aminoglycoside antibiotics. The selection agent used was kanamycin in the protoplast transformation studies, but it was not effective as many calli recovered after kanamycin selection yielded nontransformed plants (Toriyama *et al.*, 1988; Ayres and Park, 1994). A related antibiotic G418 proved more effective as evidenced by high-frequency regeneration of transgenic plants from biolistic transformation (Ayres and Park, 1994), but was still ineffective in *Agrobacterium*-mediated transformation where no transgenic regenerants were recovered (Aldemita and Hodges, 1996), possibly suggesting that prolonged exposure to G418 inhibits regeneration.

For *Agrobacterium*-mediated transformation, the selection marker of choice was hygromycin phosphotransferase (*hpt* or *aphIV* or *hph*), that confers resistance to the aminoglycoside antibiotic hygromycin (Hiei *et al.*, 1994; Dong *et al.*, 1996; Rashid *et al.*, 1996; Aldemita and Hodges, 1996). Hygromycin resistant transformed tissues typically give rise to fertile transgenic plants with few visible phenotypic abnormalities, such as albinos.

Herbicide-resistant genes are also used as selection markers, and for transgenic rice, the most widely used is the *bar* (basta-resistant) gene, that confers resistance to L-phosphinothricin (PPT), glyphosate (an ammonium salt of PPT), and bialaphos (a derivative of PPT) (Christou *et al.*, 1991; Cao *et al.*, 1992; Datta *et al.*, 1992; Rathore *et al.*, 1993).

Recent research has focused on developing selectable markers based on positive selection systems that exploit the plant's own metabolic pathways. The first in line amongst such positive selection systems was that for phosphomannose isomerase (PMI)/mannose (Privalle, 2001). PMI, an enzyme not present in many plants, catalyzes

the reversible interconversion of mannose 6-phosphate and fructose 6-phosphate. Plant cells lacking this enzyme are incapable of surviving on synthetic medium containing mannose. Introduction of this gene thus enables selection of transgenic plants on media supplemented with mannose. This selection method was successfully employed for rice (Lucca *et al.*, 2001b; Datta *et al.*, 2003; He *et al.*, 2004). Another novel selection system for rice is based on galactose as the selective agent with an UDP-glucose: galactose-1-phosphate uridylyltransferase gene providing resistance (Joersbo *et al.*, 2003). Yamada *et al.* (2004) developed a selection system based on a mutant rice gene for a feedback-insensitive α -subunit of anthranilate synthase (OASA1D) for the transformation of rice. Expression of OASA1D conferred the ability to detoxify the tryptophan analog 5-methyltryptophan (5MT) in transformed cells of rice. Dai *et al.* (2001a) employed the bacterial gene *codA* encoding cytosine deaminase (CD), which converts 5-fluorocytosine (5-FC) to 5-fluorouracil (5-FU), a compound that is toxic to cell growth. Transgenic rice plants containing the *codA* coding sequence fused with the phloem-specific promoter of rice tungro bacilliform virus were selected by the addition of 5-FC to the medium. Upadhyaya *et al.* (2000b) generated transgenic rice with the *tms2* gene, a conditional negative selection marker that encodes indoleacetic acid hydrolase (IAAH), which converts naphthaleneacetamide (NAM) to the potent auxin naphthaleneacetic acid, a phytotoxic derivative. This gene, under the control of the manopine synthase 2 promoter from *A. tumefaciens* and exogenously applied NAM was used in selecting transgenic rice. Oreifig *et al.* (2004) demonstrated the use of aminoglycoside-3'-adenyltransferase gene (*aadA*)-mediated streptomycin resistance for nonlethal selection of transgenic rice, which resulted in plant regeneration frequencies under selection pressure as high as those in nontransformed controls without selection.

Recent efforts to improve the rice transformation system have focused on marker-free selection, as this should alleviate environmental safety concerns regarding the release of unwanted resistance genes into the food crop chain. Selection systems often have other limitations. These include negative effects in culture media that decrease the

ability of transgenic cells to proliferate and to differentiate into transgenic plants. Additionally, their inclusion often precludes the use of the same marker gene for gene stacking through retransformation. Tu *et al.* (2003) demonstrated that in the recipient transgenic genome of the elite Chinese CMS restorer line Minghui 63, two independent loci are involved in the integration of the insecticidal protein gene *cryIAb/cryIAC* and selectable marker gene *hph*. The independent locus integration of the transgenes facilitated the removal of *hph* from the gene of interest simply by segregation. Cotsaftis *et al.* (2002) generated transgenic rice with the gene of interest driven by the maize ubiquitin promoter between minimal terminal inverted repeats of the maize *Ac-Ds* transposon system, which was cloned in the 5' untranslated sequence of a *gfp* gene used as an excision marker. This strategy is aimed at transposon-mediated repositioning of transgenes to generate plants that are free of selectable markers and T-DNA inserts. By using a minimal number of transformation events a large number of transgene insertions in the genome can be obtained so as to benefit from position effects in the genome that can contribute to higher levels of expression. These techniques have one major pitfall: the time-consuming exercise of progeny crossing to generate the desired marker-free transgenic plants.

Another advance in the generation of marker-free rice plants involves the MAT vector system that exploits the oncogenes of *Agrobacterium* as a positive selection marker to select transformed tissues in combination with the site-specific *R/RS* system (Endo *et al.*, 2002). The original MAT vector contains the chimeric *ipt* gene that enables regeneration of marker-free shooty phenotypes from which transgenic plants are regenerated through cytokinin-dependent organogenesis (Ebinuma *et al.*, 1997). However, this method was unsuitable for plants dependent on auxin-induced embryogenesis. The system developed by Endo *et al.* (2002) consists of a vector in which the chimeric *ipt* and *gfp* genes fused with the CaMV 35S promoter are combined with the site-specific recombination *R/RS* system, to remove them from the transgenic cells after transformation. Thus, a single-step transformation with scutellar tissues including the excision of the *ipt* gene caused the regeneration of marker-free transgenic rice plants through

embryogenic tissues. Lu *et al.* (2001) adapted an effective “twin T-DNA” binary vector (Komari *et al.*, 1996) to develop a double right border (RB) binary vector, through which transgenic plants would contain two types of T-DNA inserts, i.e., one with both the selectable gene and the gene of interest, and the other with the just the gene of interest, which were then segregated in subsequent generations to recover marker-free transgenic rice. Breitler *et al.* (2004) developed a two T-DNA vector system where the first T-DNA of the vector, delimited by *A. tumefaciens* borders, contains the *hpt* selectable gene and the *gfp* reporter gene while the second T-DNA, delimited by *Agrobacterium rhizogenes* borders, bears the *bar* gene, featuring the gene of interest. Statistical analysis identified in most of the transgenic rice lines a most likely linkage configuration theoretically allowing genetic separation of the two T-DNA types and out segregation of the T-DNA bearing the *bar* gene. The technology was successfully employed in three elite rice cultivars (ZhongZuo321, Ariete and Khao Dawk Mali 105) known to exhibit contrasting amenabilities to transformation.

In another novel dual binary vector system, pGreen/pSoup (Vain *et al.*, 2003), where, pGreen is a small Ti binary vector unable to replicate in *Agrobacterium* without the presence of another binary plasmid, pSoup, in the same strain, marker-free transgenic rice was generated. Co-transformation experiments were conducted using a pGreen vector containing the *bar* and *gusA* expression units (no transgene in pSoup) or with a pSoup vector containing an *aphIV* and *gfp* expression units (no transgene in pGreen) to generate transgenic plants with multilocus unlinked transgene integration, which would allow recovery of selectable marker-free plants in subsequent progeny.

2.4 Efficient Transgenic Plant Regeneration

A prerequisite for a high-efficiency transformation technique is a highly efficient and robust tissue culture system. Transformation processes often involve a long course of tissue culture, subcultures on medium with and without antibiotics, during which the quality of the calli may be lost. The selection of a most suitable subculture medium to improve the quality of calli and later an efficient

regeneration medium might be a key step for the success of transformation.

Transgenic rice regeneration media were mostly MS based with benzyl-aminopurine (BAP) and naphthalene acetic acid (NAA) in *Japonica*, *Indica* (Hiei *et al.*, 1994; Aldemita and Hodges, 1996; Dong *et al.*, 1996), and *Javanica* varieties (Dong *et al.*, 1996). Hormone-free MS media were used for rooting of the regenerated shoots. Inclusion of sorbitol, kinetin and casamino acids also increase efficiency of regeneration (Toki, 1997), and in some cases, an increased amount of sucrose in a pregeneration medium increases efficiency (Uze *et al.*, 1997). For increasing transgenic plant regeneration efficiency in *Indica* varieties, using MS-based media as a starting point, the relative proportions of the nutrients and the ratios of macronutrients and micronutrients were changed taking into account the bioavailability of the nutrients under a given pH range (Lin and Zhang, 2004). Maltose proved to be better than sucrose as the carbohydrate source in both the subculture and differentiation media for *Indica* rice (Lin and Zhang, 2004). Toki *et al.* (2006) designed an efficient protocol, where 1-day precultured seeds were used for transformation, from which transformants were regenerated within 30 days of the beginning of the culture. Regenerated plantlets were transferred to soil at 45 days from the beginning of culture and further grown to maturity. The addition of proline in the culture media in both co-cultivation and regeneration steps, and maintaining cultures at 32 °C was further thought to assist in the recovery of rice cell growth after co-culture with *Agrobacterium*. To recover multiple independent transgenic events from a single immature embryo, Hiei and Komari (2006) devised a procedure, where a rice embryo was sectioned into as many as 30 pieces after nonselective cultures following co-cultivation. Following selection, more than seven independent transgenic plants per original embryo (transformation frequency of 738%) were produced.

Nishimura *et al.* (2005) conducted conventional crosses of low-regeneration rice strain Koshihikari with high-regeneration rice strain Kasalath and identified some QTLs, which control the regeneration ability in rice. Using a map-based cloning strategy, a QTL encoding ferredoxin nitrite reductase (NiR) that determines regeneration

ability in rice was isolated. Molecular analyses revealed that the poor regeneration ability of Koshihikari is caused by lower expression than in Kasalath and the specific activity of NiR. Using the *NiR* gene as a selection marker, transgenic rice was regenerated without exogenous marker genes. This study demonstrates that nitrate assimilation is an important process in rice regeneration and also provides an additional selectable marker for rice transformation.

2.5 Transgene Expression: The Phenomenon of Transgene Silencing

Successful plant genetic engineering relies on stable integration, desired level of expression, and predictable inheritance of the introduced transgenes. A comparative analysis of transgenic rice plants obtained by *Agrobacterium*-mediated transformation and particle bombardment (Dai *et al.*, 2001b) showed that *Agrobacterium* method was a good system to obtain transgenic plants with lower copy number (an average of 1.8 as compared to 2.7 in case of particle bombardment), intact foreign gene, and stable gene expression. T-DNA generally integrates into gene-rich transcriptionally active regions of the rice genome (Barakat *et al.*, 2000; Sha *et al.*, 2004), and on occasions cause integration of multiple elements in various patterns of inverted or tandem repeats (De Buck *et al.*, 2000; Eamens *et al.*, 2004).

Transgenic lines from particle bombardment generally have multiple copy integrations at a single locus frequently displaying non-Mendelian segregation (Pawlowski and Somers, 1996; Kumpatla *et al.*, 1997; Kohli *et al.*, 1998; Kumpatla and Hall, 1999) and are prone to the phenomenon of gene silencing. Transgene silencing could be a consequence of transcription inactivation by promoter methylation, known as transcriptional gene silencing (TGS) or through post-transcriptional gene silencing (PTGS) characterized by specific reduction of cytoplasmic RNA through sequence-specific degradation, with normal rates of nuclear transcription being maintained (Vaucheret *et al.*, 1998). Gene silencing is frequent in transgenic rice generated by particle bombardment (Iyer *et al.*, 2000; Tyagi and Mohanty, 2000).

Kohli *et al.* (1998) proposed that transgene organization in rice engineered through direct

DNA transfer favors a two-phase integration mechanism mediated by the establishment of integration hotspots. This model, together with the exonuclease/ligase model (McElroy *et al.*, 1990) suggests a possible explanation for the occurrence of multicopies of genes located at a single locus in transgenic plants generated by particle bombardment. Kloti *et al.* (2002) demonstrated tissue-specific silencing in rice spread to various organs over generations.

An extensive investigation of several hundred transgenic plants generated by electroporation or particle bombardment revealed that transformants bearing multicopy inserts frequently displayed non-Mendelian segregation (Kumpatla *et al.*, 1997; Kumpatla and Hall, 1999), and characterization of several R₁ progeny revealed that *mUbl1/bar* and *35S/Bt* genes were extensively methylated and transcriptionally inactivated in the silenced lines. The epigenetic modification of the transgene sequences was further confirmed by the reactivation of the *bar* gene expression in R₂ seedlings (from the silenced lines) germinated on medium containing the demethylating agent 5-azacytidine (AzaC) or trichostatin (Kumpatla *et al.*, 1997). It appears that, once a locus is sensitized to methylation, it is rendered very prone to methylation. This was exemplified in an investigation of 34 R₂ plants in which bialaphos resistance was reactivated by seedling exposure to AzaC; however, all except one were resilenced by 50 days after germination. The single line that retained resistance to maturity did not set seed, and after maintenance in the greenhouse for over a year, set seed which when germinated yielded the silent phenotype. Re-establishment of silencing in all the lines was found to correlate in each case with methylation of the ubiquitin promoter (Kumpatla and Hall, 1998a, b), and in a homozygous, nonsilenced R₁ line, promoter methylation and silencing may arise in R₃ generation (Kumpatla and Hall, 1998a, b). Several sites in the 35S promoter that is widely used in transformation are susceptible to fragmentation (Kohli *et al.*, 1999a; Kumpatla and Hall, 1999). The possibility that certain sequences are especially prone to silencing was proved with the root-specific rice *Rcg2* promoter (Xu *et al.*, 1995), which showed transgene silencing even though *Agrobacterium*-mediated transformation was used (Dong *et al.*, 1996). The reactivation of silencing by AzaC

and a meiotic resetting of *Rcg2-uidA* construct was not uniform amongst transgenic lines or even throughout individual plants, indicating that various silencing mechanisms may operate and that the chromosomal position of the transgene may affect the silencing processes (Hall *et al.*, 2001). Fu *et al.* (2000b) discovered that three transgenes at a co-integrate locus along three generations exhibited differential silencing and differential methylation patterns, which did not spread to the flanking transgene, thus confirming that various silencing mechanisms may be operative within the locus.

Other DNA features such as sequential and structural differences between the prokaryotic and eukaryotic DNA, have been suggested as signals that could lead to transgene sequences being recognized by host surveillance systems as intrusive (Kumapatla *et al.*, 1998a, b). Fu *et al.* (2000a) demonstrated that the use of linear transgene constructs lacking vector backbones was very effective in reducing the occurrence of transgene silencing in rice transformation.

Multicopy insertions are susceptible to silencing, and epistatic interactions between multicopy and single copy inserts were shown to silence transgenes in rice, when a single copy gene at one locus was silenced in the presence of locus bearing multiple transgene copies (Hall *et al.*, 2001). The segregation from the multiple transgene locus resulted in reactivation of the gene at the single copy locus reminiscent of paramutation where a paramutated locus regains expression when segregate away from a paramutagenic locus (Matzke *et al.*, 1996).

Alleviation of transgene silencing can be achieved by various strategies such as introduction of sequence heterogeneity in promoters (Kumapatla *et al.*, 1998a, b), suppression of methylation systems and reduction for heterochromatization by insertion of enhancer elements (Francastel *et al.*, 1999), and inclusion of MARs resulting in improved transgene expression in copy numbers up to 20 copies (Vain *et al.*, 1999).

2.6 Transgenic Rice Biotechnology: Important Milestones

Introduction of agronomically important genes into rice by breeders worldwide has contributed to record yields and resistant crops tiding over

both biotic and abiotic stresses to combat global food shortage to meet the predicted demands of increasing population, a fact corroborated by the achievements of the green revolution movement. It is now projected that by the year 2012, rice production needs to increase by 755 million tons (Brookes and Barfoot, 2003). The housing and habitation demands of the increasing population in the developing world has led to sacrificing the farming and crop cultivation areas in favor of residential development (Fischer *et al.*, 2000), and hence the viable option of increasing the areas of rice cultivation is becoming more and more difficult. This is the reason for shaping a vision for a second green revolution (Sakamoto and Matsuoka, 2004) where, rice breeding efforts need to be supplemented with advances in biotechnology especially the introduction of agronomically important genes through genetic transformation. The technology of genetic transformation when the first reports of introducing agronomically important genes in rice dates back to 14 years and the advances in the field show a significant progress (Bajaj and Mohanty, 2005; Kathuria *et al.*, 2007). The preceding account highlights the important milestones in this area.

2.6.1 The first reports

Hayakawa *et al.* (1992) generated the first transgenic rice plants with an agronomically important gene by introducing the CP gene of RSV into two *Japonica* varieties by electroporation of protoplasts. The resultant transgenic plants expressed the CP at high levels (upto 0.5% of total soluble protein) and exhibited a significant level of resistance to virus infection transmitted by an insect vector (planthopper). Fujimoto *et al.* (1993) developed insect-resistant transgenic rice by introducing a truncated δ -endotoxin gene, *cryIAb* of *B. thuringiensis* (*Bt*), which has specific biological activity against lepidopteran insects into *Japonica* rice. To highly express the *cryIAb* gene in rice, the coding sequence was extensively modified based on the codon usage of rice genes. Transgenic plants efficiently expressed the modified *cryIAb* gene at both messenger-RNA (mRNA) and protein levels. Bioassays using R₂ generation plants with two major rice insect pests, striped stem borer (*C. suppressalis*) and leaf folder (*C. medinalis*). Uchimiya *et al.* (1993) developed

bialaphos-resistant rice plants expressing a *bar* gene under the control of the maize ubiquitin promoter, which when inoculated with mycelia of the sheath blight disease pathogen, *R. solani*, and subsequently treated with the herbicide were completely protected from symptomatic infection. This report demonstrated the possibility to design new agronomic strategies for the simultaneous control of weeds and fungal pathogens in fields of transgenic plants expressing a *bar* gene.

2.6.2 Rockefeller Foundation's rice biotechnology program: the saga of Xa21-engineered transgenic rice

The story of the bacterial blight resistance gene *Xa21*-engineered transgenic rice epitomizes the International Program on Rice Biotechnology (IPRB) initiated by the Rockefeller Foundation to exploit the scientific tools of biotechnology in improving rice, and extends the knowledge generation from the program goals to production of improved rice varieties (O'Toole *et al.*, 2001). The scientific saga also serves as an illustrative example of how the knowledge of traditional breeding and biotechnology complement each other in generating disease-resistant rice.

In 1977, *Oryza longistaminata* lines originating from Mali, Africa were identified to carry broad-spectrum resistance to bacterial blight. Khush *et al.* (1991) transferred *Xa21* into *O. sativa* background through interspecific hybridization. Ronald *et al.* (1992) mapped the *Xa21* locus by the restriction fragment length polymorphism technique. Map-based cloning of the gene via BAC library construction (Wang *et al.*, 1995) was followed by the *Xa21* isolation by positional cloning, sequencing, and demonstration of resistance to multiple *X. oryzae* pv. *oryzae* isolates in transgenic rice plants (Song *et al.*, 1995; Wang *et al.*, 1996). The *Xa21* gene was then pyramided with other *Xa* R genes by marker-assisted selection using RFLP and PCR (Huang *et al.*, 1997; Reddy *et al.*, 1997). Tu *et al.* (1998) transferred *Xa21* into the IR72 variety, and later Zhang *et al.* (1998) developed other elite transgenic *Indica* varieties resistant to *X. oryzae* pv. *oryzae*. The first field trials of *Xa* genes, including *Xa21* were reported in China, India, Indonesia, and the Philippines (Rockefeller Foundation, 1999). The final achievement of this scientific saga climaxed with the development

of a commercial hybrid restorer line genetically improved by marker-assisted selection of *Xa21* and the resulting hybrid rice "Minghui 63" demonstrating field level efficiency in combating bacterial blight (Chen *et al.*, 2000).

2.6.3 Insect-resistant transgenic rice

After the first report of insect-resistant *Bt*-transgenic rice (Fujimoto *et al.*, 1993), Wunn *et al.* (1996) developed transgenic *Indica* rice breeding line IR58 expressing a synthetic *cryIAb* gene providing tolerance to several lepidopteran insect pests. Duan *et al.* (1996) engineered the potato proteinase inhibitor II (*pinII*) gene in Nipponbare, Tainung, and Pi4 varieties for resistance to a major insect pest, pink stem borer. The first report of *Agrobacterium*-mediated rice transformation for an agronomically important gene was with insect-resistant *cryIAb* and *cryIIAc* genes to generate transgenic Nipponbare varieties resistant to striped stem borer and yellow stem borer (Cheng *et al.*, 1998). The first field trials of *Bt*-transgenic rice were with transgenic Minghui 63 and Shanyou 63, which showed high insect resistance with no reduction in yield toward leaf folder and yellow stem borer (Tu *et al.*, 2000). The same year was witness to successful field trials of the transgenic KMD1 line of a Chinese *Japonica* cultivar, Xuishi 11, which was resistant to eight lepidopteran pests (Shu *et al.*, 2000). KMD1 and related transgenic lines were also used as insect-resistant rice germplasm for hybrid rice production (Wang *et al.*, 2002).

High *et al.* (2004) suggested that *Bt* rice could contribute in circumventing up to 10% of the Asian rice yield losses caused by the lepidopteran pests. For providing wider and durable resistance to insect pests, combinations of *Bt* with other insecticidal genes sourced from plants themselves such as lectins, protease inhibitors, or ribosome inactivating proteins proved effective (Sharma *et al.*, 2004; Bajaj and Mohanty, 2005).

2.6.4 Nutritionally enhanced "Golden Rice"

Research focused on nutritional enhancement of rice will have a significant impact on the needs of global population, as close to 3.8 billion

people consume it as a staple component of their daily diet. The nutritional component, which attracted major research attention, was β -carotene (provitamin A) due to its absence in milled rice. The increased consumption of this component in daily diet could potentially prevent an estimated 3 million childhood eye defects and even deaths annually (Bouis *et al.*, 2003). Engineering rice with enhanced micronutrient content is hoped to circumvent the global micronutrient underconsumption, as the high costs of supplementary micronutrient-rich nonstaple foods like fruits, vegetables, animal and fish products, and pulses are beyond the reach of millions in the developing countries (Zimmermann and Hurrell, 2002; Bouis *et al.*, 2003).

The research groups of Ingo Potrykus at Swiss Federal Institute of Technology and Peter Beyer, University of Freiberg pioneered the research on provitamin A-enriched rice popularly known as “Golden Rice.” The first step in this research was the generation of transgenic rice with daffodil phytoene synthase gene (Burkhardt *et al.*, 1997). Later, the entire biosynthetic pathway for provitamin A was engineered in the rice endosperm in a single transformation step using phytoene synthase gene (*PSY*) and lycopene β -cyclase gene (*LCY*) from daffodil and phytoene desaturase gene (*crt1*) from bacterium, *Erwinia uredovora* (Ye *et al.*, 2000). Later, it was found that the entire pathway could be reconstituted using only the *PSY* and *crt1* genes in *Indica* and *Japonica* varieties (Hoa *et al.*, 2003), using nonantibiotic mannose-based selection systems (Datta *et al.*, 2003). Later research focused on tiding over limitations and the debate on carotenoid requirements formed in Golden Rice (Bouis *et al.*, 2003; Zimmermann and Qaim, 2004). The use of a codon-optimized *crt1* gene under the control of an endosperm-specific promoter (Al-Babili *et al.*, 2006) and use of maize *PSY* gene (Paine *et al.*, 2005) enhanced the transgenic rice carotenoid content up to 37 $\mu\text{g/g}$ in “Golden Rice-2”, a move now proposed to further improve provitamin A production in rice (Grusak, 2005). An international effort is currently underway to exploit this improved pathway technology in popular rice cultivars of the developing countries (Potrykus, 2001). As a significant step in this direction, Datta *et al.* (2006) developed transgenic high-yielding elite *Indica* rice varieties IR64 and

BR29 with carotenoid content of as high as 9.3 $\mu\text{g/g}$.

2.7 Transgenic Plant Regulation: Biosafety Regulations and Environmental Risks of Transgenic Rice

Release of genetically modified food-crop plants has been a sensitive issue with various stakeholders and the public opinion on it is divided. Most developing countries, where rice is the staple crop for a large number of poor people, welcome transgenic rice both at the public and the government level. Main evidence for this is that most Asian and African countries already have working biosafety regulations for field-testing transgenic crops. Transgenic rice resistant to insect, bacteria, and herbicides has undergone field trials to test for economic profitability and environmental impacts (Oard *et al.*, 1996; Tu *et al.*, 2000; Ye *et al.*, 2001, 2003; Bashir *et al.*, 2004; Huang *et al.*, 2005). Although most of these trials were conducted with transgenic rice containing the vector sequences including the marker and reporter genes, there is indeed a shift to generating transgenic rice without the unnecessary vector and marker sequences. The tools and techniques used toward this aim have been outlined earlier in the chapter. Additional strategies to use endogenous benign selection markers have been explored, for example, genes specific for allowing regeneration in the absence of phytohormones (Zuo *et al.*, 2002), the phosphomannose isomerase (Lucca *et al.*, 2001b), the betaine aldehyde dehydrogenase (Daniell and Dhingra, 2002) or the NiR (Nishimura *et al.*, 2005). A number of reports suggest that there may be no unintended effects of the transgenic rice either within the plant or in the environment (Momma *et al.*, 2000; Wang *et al.*, 2000; Xu *et al.*, 2002; Li *et al.*, 2004; Wang *et al.*, 2006). However, the complexity of the matter in combination with intellectual property rights (IPR) issues is evident from the fact that “Golden Rice” is still not close to being commercialized.

3. FUTURE ROAD MAP

The importance of rice as one of the three important cereal crops in the world can be seen

from the fact that the worldwide produce amounts to more than 600 million tons, and more than 90% of the produce is for human consumption (Kathuria *et al.*, 2007). Since, more than half of the global population derives a significant portion of their caloric intake from rice, it is of utmost importance to focus biotechnological innovations in this crop toward continuous efforts to isolate novel genes and promoters with a view to generating novel transgenic lines with enhanced plant vigor, maximized crop yields, and better tolerance to various abiotic/biotic stresses. The World health Organization estimates that global population would reach 9 billion by 2050, the vast majority forecasted in developing countries of South-East Asia and sub-Saharan Africa. This necessitates biotechnological research in rice toward development of rice cultivars of higher yield potential to achieve higher food production on essentially the limited available land prone to drought, salt, and temperature stresses. Efforts in adapting transgenic rice technology into the mainstream population can already be seen in China, which was the first country to commercialize transgenic rice. The main focus of their efforts was to develop insect-pest-tolerant transgenic rice varieties, and already large-scale field trials since 1998 (Jia *et al.*, 2004) were carried out with several transgenic varieties tolerant to lepidopteran pests, bacterial blight, rice blast fungus, drought, and salt stress. The wide acceptance of transgenic rice in China is hoped to trigger a worldwide acceptance of the transgenic rice especially in the developing countries where rice is a staple crop. The success stories of transgenic rice varieties GM Xianyou 63 and GM-II-Youming 86 (Huang *et al.*, 2005) that require only 20% pesticides compared to untransformed controls, combined with a 6% increase in yield, is a clear testimony of creating environment-friendly rice plants that are of economic benefit to the farmers of the developing countries. A projection of a net gain of 4 billion dollars by China from *Bt* rice by 2010, has triggered cascade of effects in acceptance of transgenic rice in Iran, where 4000 ha are now growing transgenic rice (www.isaaa.org) and in India, where transfer of the “Golden Rice” trait is being taken up in popular rice cultivars (Datta *et al.*, 2003; Hoa *et al.*, 2003). It is now expected that by 2012, up to seven transgenic rice varieties including traits

like herbicide tolerance, disease resistance, abiotic stress tolerance, and nutritional enhancement will be marketed worldwide.

3.1 Expected Products

Transgenic rice technology has crossed the point of a laboratory proof of concept to actually supplement traditional breeder innovations to meet global nutritional demands. This is reflected in the form of the wide spread field trials of insect- and herbicide-tolerant rice in United States, China, South Asia, and the Mediterranean (Bajaj and Mohanty, 2005).

The committed research focus of developing countries like India toward adopting “Golden Rice” technology (Potrykus, 2001; Sharma *et al.*, 2003), has resulted in a projection that provitamin A-enhanced rice would be available for consumers in the developing world within the next 7–8 years (Brookes and Barfoot, 2003).

Efforts made in improving yield by targeting genes like ADP-glucose pyrophosphorylase, which increases seed weight per plant (Smidansky *et al.*, 2003), and transfer of C4 plant genes into rice, which is a C3 plant with an aim to increase photosynthetic efficiency and yield (Matsuoka *et al.*, 1993; Ku *et al.*, 1999), expression of *Arabidopsis* phytochrome A gene to increase yield (Garg *et al.*, 2006) have opened doors for future research in improving grain yields.

3.1.1 Rice as a biofactory

Due to the genomics, transformation and tissue culture resources available for rice and its simple life cycle under varied climatic conditions and standardized agronomic practices, rice has recently acquired the status of biofactory for the production of high-value pharmaceutical or nutraceutical compounds. Additional advantages of producing such compounds in plants rather than the microbes are post-translational modification of the proteins, increased safety for human consumption, extraction and purification cost benefits and storage benefits in seed endosperm (Stoger *et al.*, 2000; Twyman *et al.*, 2003). A number of high-value products have been produced in transgenic rice like a single chain Fv antibody against

a tumor-associated carcinoembryonic antigen (Stoger *et al.*, 2000), human lactoferrin (Nandi *et al.*, 2002; Suzuki *et al.*, 2003), transglutaminase (Claparols *et al.*, 2004), N-hydroxycinnamoyl transferase (Jang *et al.*, 2004), lupin acid phosphatase (Hamada *et al.*, 2004), human lysozyme (Huang *et al.*, 2002a, b; Hennegan *et al.*, 2005), glycogenlike peptide for type II diabetes treatment (Yasuda *et al.*, 2005), recombinant pollen allergen (Okada *et al.*, 2003); linolenic isomers, which reduce fat and hypertension (Kohno-Murase *et al.*, 2006); allergen-specific T-cell epitope (Takagi *et al.*, 2005), and the human granulocyte colony stimulating factor (Hong *et al.*, 2006), antihypertensive peptide fused with rice glutelin (Yang *et al.*, 2006). These examples establish transgenic rice as an ideal model for future pharmaceutical and nutraceutical applications.

3.2 Expected Technologies

Technological innovations in transgenic rice technology have always been geared toward achieving a maximized and targeted expression of transgenes. Novel promoters to achieve high levels of transgene expression like the bacteriophage T7 polymerase (Nguyen *et al.*, 2004), TM2, a novel strong MAR isolated from tobacco (Xue *et al.*, 2005) were shown to increase transgene expression to higher levels compared to traditional promoters like CaMV 35S promoter.

3.2.1 Rice as a model for cereal genome function studies

The complete rice genome sequence has opened up enormous possibilities of map-based cloning of several agronomically important genes. The most significant example of exploiting the information from the completely sequenced rice genome is the analysis throwing up several orthologs of *Arabidopsis* flowering time genes (Goff *et al.*, 2002), which would be of significance when developing high-yielding rice varieties. A high-throughput fluorescent tagging of full-length *Arabidopsis* gene products *in planta* (Tian *et al.*, 2004) could be adapted to analyze proteins of unknown function in the now available complete rice genome sequence. Hirochika *et al.* (2004)

developed a rich resource for mutants for gene discovery in rice, which would enable functional analysis of most of the rice genes. The Rice Full Length cDNA Consortium developed in 2003 has enabled access to nearly 28 000 full-length cDNAs, which when transgenically analyzed aided by the RNA interference (RNAi) approach would aid in deciphering important gene functions.

Sequencing of the rice genome along with generating populations of genome saturation mutagenesis, provides the opportunity to take our understanding of cereal cellular processes and networks to the next level and integrate rice improvement as a crop, as a model plant, and as a plant biofactory. Nearly 38 000 proteins have been annotated in the rice genome, and for more than half of them, functions have not been elucidated. It is also clear that a number of proteins are a part of one or more cellular pathway(s) and hence their function linked to, and to a certain extent dictated by, the function of other proteins. Elucidating these functions and interconnections is most easily possible through specific mutagenesis and/or silencing studies. For mutagenesis studies as well as for generating appropriate transgenic lines, homologous recombination would be the ideal tool. However, very limited success has been achieved with this approach in rice using the recombinase systems available (Cotsaftis and Guiderdoni, 2005). The largely random integration methods of *Agrobacterium*- and biolistics-mediated transformation systems have been used to generate saturation-mutagenized populations of *Indica* and *Japonica* rice. Different reporter genes such as the *gus*, *gfp*, *luc*, and the anthocyanin synthesis *R* gene have been used in coordination with different retrotransposon systems, e.g., *Ac/Ds* (Chin *et al.*, 1999; Enoki *et al.*, 1999; Kohli *et al.*, 2001; Greco *et al.*, 2001; Kolesnik *et al.*, 2004; Upadhyaya *et al.*, 2006), *Tos17* (Hirochika, 2004) or *T-DNA* (Jeon *et al.*, 2000; An *et al.*, 2005a, b) to generate these populations. A number of novel and important genes have been identified using these populations (reviewed in Hirochika *et al.*, 2005; Kathuria *et al.*, 2007), including genes controlling plant height, cellulose synthesis, cell elongation (Zhou *et al.*, 2006), gibberellic acid synthesis gene (Margis-Pinheiro *et al.*, 2005), blast resistance gene (Kim *et al.*, 2003), and pollen development gene (Han *et al.*, 2006).

The now reliable method of gene silencing as a supplementary technology to gene mutation for confirming their role and effects on the plant was discovered as an undesirable trait. Transgenes integrated in plants would stop expressing the protein product or even the mRNA. The phenomenon was first reported in plants such as petunia and tobacco in the early 1990s (Decarvalho *et al.*, 1992; Renckens *et al.*, 1992). The first reports of transgene silencing and its reactivation by 5-azacytidine in rice (Kohli *et al.*, 1996; Kumpatla *et al.*, 1997) paved the way for further gene silencing studies in rice (Kumpatla and Hall, 1998a, b; Fu *et al.*, 2000b). Recent reviews (Kohli *et al.*, 2003, 2006) describe comprehensively various DNA, mRNA, and protein-related factors that contribute to transgene silencing. As a result of extensive studies on transgene and endogenous gene silencing in transgenic plants, methods of RNAi were established to interrogate the role of endogenous genes. RNAi vectors for transient and stable suppression of gene function in rice have been reported (Miki and Shimamoto, 2004; Wang *et al.*, 2004) and the technology has been used to investigate the role of agronomically important genes in rice, for example the silencing of *OSGEN-L*, which causes male sterility (Moritoh *et al.*, 2005). Recent reviews by Mansoor *et al.* (2006) and Kusaba (2004) cite additional examples where the RNAi technology of gene silencing has led to information on the role of different genes in different plants including rice.

3.3 Public, Industrial, Political, and Economic Consequences

There is no doubt about the powerful role of molecular biology and biotechnology in rice improvement for future generations since it directly feeds into the fast-tracked and marker-assisted breeding efforts to generate varieties that yield enough to feed the rising populations. The transgenic technologies can indeed directly generate varieties with desired characteristics but more importantly the transgenic technology is useful for discovering, isolating, and assessing new genes and regulatory elements to understand the genomics and proteomics networks. Such an understanding can in turn lead to fast-tracked

molecular breeding efforts. For what it can deliver in terms of alleviating hunger and poverty, the technology cannot be allowed to stagnate when its use is already showing its potentials (Brookes and Barfoot, 2003; James, 2005). However, at the same time, a rigorous safety, regulatory, surveillance, and risk management strategy must be formulated to ally any public fears.

Major National agencies such as the Animal and Plant Health Inspection Service (APHIS), Food and Drug Administration (FDA), and the Environmental Protection Agency (EPA) in the United States and institute level bodies such as the Institutional Biosafety Committee (IBC) play a role in evaluating the transgenic crop plants for release. For issues involved in biosafety of the transgenic crops, a good resource is the <http://usbiotechreg.nbi.gov> Web site. Research on and release of a transgenic crop spans an entire spectrum of personnel that are in any way connected to such research as for example, starting from the green house manager at the research center, up to the national certification bodies. One of the recent concerns in any applications seeking research or field test permission is the requirement to submit maximum information scientific and otherwise, whether relevant to risk assessment or not. This is not in the interest of the technology or the public. Guidelines are now being increasingly available on what aspects of the research and research product information must be included to make reasonable risk assessment without having to provide reams of unnecessary documentation (www.pubresreg.org). A number of European Union (EU) framework program grants have been funded over the last 8 years under the Quality of Life and Management of Living Resources to address the science and social science aspects of biosafety of GM crops including rice. A collection of reports and papers of the five working groups addressing safety testing, detection of unintended effects, gene transfer, traceability, and societal aspects has been published in two special volumes of the Food and Chemical Toxicology (Kuiper *et al.*, 2004). Surveys conducted at the EU level at regular intervals indicate that the overall public attitude to GM crops is neutral although people in some specific countries may be more for or against the technology (Frewer *et al.*, 2004).

Field tests for “Golden Rice” have been conducted in India, the Philippines, and Vietnam.

However an overzealous precautionary approach has limited the opportunity of commercializing it despite major hurdles on the IPR front being deftly negotiated through the involvement of a consortium of private and public stakeholders including major rice research and breeding centers in Asia.

Acceptance of transgenic rice in developing countries will enable governments of other neighboring countries also to take a stand considering the potential economic and human resource benefits. Additionally, rice is being increasingly used in molecular farming enterprises and its genomics resources are once again erecting it as a model to study cell wall synthesis and breakdown for the biofuels industry. Most plant-based bioethanol projects are centered on cereals/grasses such as *Miscanthus*, sweet sorghum, maize, etc. In view of these developments the transgenic technology of rice crop points toward a bright future.

4. CONCLUSION: RICE—A MODEL MONOCOT

A small genome, an efficient transformation technology, a comprehensive physical map and more recently, the complete genome sequence made rice achieve the status of a “model monocot”. Information gleaned from the genome is currently being utilized to understand fundamental aspects of growth, development, and physiology of the plant kingdom. The functional aspects range from elucidation of individual gene function to deciphering and engineering metabolic pathways. The extensive ancestral synteny shared by rice with other cereals enables its exploitation in designing research to genetically improve other related cereals with larger genomes like maize, wheat, and barley.

1. INTRODUCTION

The commercial application of agricultural biotechnology in corn has primarily focused on the development of “input traits”, which provide attributes beneficial to the grower. Examples of licensed products comprise herbicide and pest resistance traits with others such as disease, drought, salinity, and cold resistance, and enhanced photosynthesis and nitrogen fixation under development. Because input traits improve crop production, agricultural companies have leveraged the technology to maintain and expand market share.

Biotechnology is also enabling the creation of new products, called “output traits”, aimed at the farmer’s downstream customers. Such traits may provide improved nutritional qualities for animal feed, healthier and more flavorful foods, specialty chemical and biologic compounds, or improved processing capabilities (Shoemaker *et al.*, 2001). Two specific examples are Syngenta’s corn amylase and phytase varieties with embedded enzymes for improved ethanol production and increased utilization of phytate in animal feed (Kemble, 2006). Such opportunities remain largely unmet in the market place, thereby providing new growth areas for agricultural biotechnology companies and promising to provide benefits for agricultural processors and consumers. While output traits

will still be used to expand market share, they will provide potentially greater downstream value and will require new business models based upon thorough analyses of each specific target industry to determine the best approaches for value capture.

Corn ethanol production in the United States is one area where biotechnology may be applied to dramatically decrease costs, improve energy input requirements, and expand capacity. Numerous opportunities exist for improving important characteristics of the corn plant to decrease the cost of producing ethanol. However, the cost of developing a biotechnology crop with approval from the appropriate regulatory authorities is high. Therefore, these opportunities must be analyzed in an industrial context, understanding the market size, growth and potential return to ensure that the most value is created in the shortest period of time.

Regardless of the plant chosen to be manipulated through biotechnology for ethanol production, four technological platforms must be in place. Firstly, robust tissue culture protocols must be in place that couple the production of large numbers of regenerated plants with substantive reductions in the timing of the life cycle. Secondly, this tissue culture technology in turn must be linked to high-frequency DNA transfer whereby the cell competent to regenerate is likewise competent with respect to nucleic acid uptake. Thirdly, the genes and/or their promoters

that increase some aspect of ethanol production should be amenable to expression optimization. Finally, a processing technology must be in place that maximizes the recovery of ethanol. In this chapter, the advances in maize tissue culture and transformation, in gene discovery and expression optimization, and maize ethanol processing are reviewed. The position affirmed here is that technical advances in maize biotechnology make it today's model plant for ethanol recovery.

1.1 History, Origin, and Distribution

Maize (*Zea mays* ssp. *mays*) originated from "teosinte" following mutation and recognition by man that this change should be capitalized upon through a conscious breeding effort. In fact, it has been argued that the derivation of corn from teosinte is man's first and most significant achievement of genetic engineering (Grun and Federoff, 2004). Maize is thought to have originated in Mexico and can be traced minimally back to at least 5000 years BC. (Jugenheimer, 1976; Brenner, 1991). Cultivation of maize and the expansion of its food products are the base structure of the pre-Colombian Mesoamerican civilizations. Commercial maize is cultivated from latitude 50°N to 40°S. Given this, modern maize can adapt to different climates and soil types. Currently, maize is cultivated throughout the world, in tropical and temperate climates, and it is considered to be the third most planted crop after wheat and rice (Wallace and Brown, 1988; Brenner, 1991).

1.2 Botanical Description

Maize is a cross-pollinating species and thus morphological variability is common among the different geographies where it is grown. The height of the plant may range from 0.6 to 6 m but usually it reaches 2.4 meters. Most of the varieties mature in 100 to 140 days from planting and produce one to three ears per plant, averaging 800 kernels per ear. The kernel number, in part, depends on ear length and yield ranges from 0.5 to 23.5 tons of grain per hectare.

Soil moisture and temperature are important factors in maize germination and early plant growth. At temperatures of 10°C and lower, maize growth is significantly impaired. Optimal maize

growth occurs at 27°C, under conditions of limited soil moisture, and 35°C, when soil water content is optimal. Cool, humid, and cloudy conditions will inhibit pollen production. In general, pollen shedding begins approximately 2 to 3 days before the silks emerge. The tassel continues to shed for another 5 to 8 days. The silks, in contrast, begin the elongation 7 to 10 days before emergence. Maize requires approximately 50 cm of water during the growing season and drought conditions, as expected, seriously impair seed set (Aldrich *et al.*, 1975). In this connection, America's Corn Belt drives its productivity through the fortuitous combination of moderate temperatures coupled with substantial rainfall and soil with ideal moisture-holding capacity.

The genus *Zea* is a grass that belongs to the family Gramineae. *Zea mays* is the most common cultivated species among other species including *Z. diploperennis*, *Z. luxurians*, and *Z. perennis*. *Zea* species are diploids with $n = 10$ chromosomes. A wide assortment of chromosome knobs, inversions, translocations, duplications, polyploids, and trisomic lines have been long available to maize workers and have, in no small way, contributed to the rapid progress of maize genome mapping. Indeed, it was the availability of this material that allowed Creighton and McClintock (1931) to show that crossing over accompanied the physical exchange of chromosome segments to show that genomes were not stable but segments thereof could move from one location to another. The utility of these chromosomal aberrations is limited in that it gives a global understanding as to how the genome is organized but little information of the organization of gene distribution.

The sophisticated information gathered from the publicly funded maize sequencing and database efforts has contributed greatly to our detailed understanding (Chandler and Brendel, 2002; Lawrence *et al.*, 2004). The corn genome is large, in fact six times larger than that of rice, and comprises 2.5 Mb. Notably, the genes comprise only 20% of the genome. The genes are not distributed randomly as a function of chromosome length but rather in a clusterlike fashion. Between these clusters are conserved high copy number retrotransposons, in addition to other repetitive sequences. The gene blocks themselves vary in size and may be likened to isolated islands surrounded by oceans of recurring DNA sequences. Indeed,

Figure 1 Corn world production for 2005–2006 [Reproduced from NCGA (2006)]

Messing *et al.* (2004), using 475 000 bacterial artificial chromosome end sequences, concluded that a significant portion of the maize gene set consists of randomly arrayed gene families.

1.3 Economic Importance

Maize is one of the most important commercial cereal crops in the world. The major maize production concentrated in the United States, China, Europe, Brazil, and Mexico collectively. These countries account for approximately 77% of the world's annual maize production. The United States alone is responsible for 41.3% of this production (Figure 1).

The most useful part of maize is the kernel. The kernel consists of the endosperm and the embryo and is produced following double fertilization. One sperm fertilizes the egg and gives rise to the diploid embryo, whereas the second sperm fertilizes the

polar nuclei, resulting in the production of a triploid endosperm. The pericarp is the tissue that surrounds the seed and is of maternal origin.

The endosperm is the primary storage tissue for starch and proteins that are essential for seed germination and is equal to approximately 82% of kernel's dry weight. The starch is a source of food, sweeteners, bioplastics, and fuel in addition to other industrial uses. Maize is the most significant crop in the United States with a value of 21.1 billion dollars. Nearly 81.8 million acres were planted throughout the United States in 2005. About 55.5% of the grain corn produced in the United States is fed to livestock, whereas approximately 17.1% of grain corn is exported either as grain or corn product. The remaining 14.6% is used to produce ethanol and 12.8% is processed. Processed products include starch, corn sugar, corn oil, gluten feed and meal, whiskey, alcohol, and for corn meals, corn flakes, etc. (Figure 2).

Figure 2 Usages of corn in the United States for 2005 [Reproduced from NCGA (2006)]

The maize market is experiencing change due to a high demand for ethanol. In consequence, the per-bushel price of corn is likely to rise as the grain is shifted from its traditional uses over to biofuel production. Indeed, recent estimates hold that corn directed toward ethanol production is expected to bring \$4.00/bushel.

1.4 Traditional Breeding

While classical breeding programs have produced high-income seed lines, tolerant and/or resistant to abiotic and biotic stresses, their synthesis is time consuming and beset many difficulties including linkage drag. Marker-assisted breeding (MAB) has vastly simplified plant breeding. From an operational point of view, molecular markers define regions of the chromosome to which a gene is linked. The lower the frequency of crossing over, the fewer the recombinants and the tighter the linkage is between the marker and the gene of interest. Thus, in the absence recombination, the transmission of a particular DNA marker co-segregates with a gene 100% of the time. Hence, the presence of marker, as determined by DNA hybridization, establishes the inheritance of the gene.

The application of MAB in maize is well established. Since the earlier 1990s, maize workers had available to them a core set of restriction fragment length polymorphism markers that marked the maize genome, available from the University of Missouri. Hosts of other markers have since been developed and their availability and description are posted on the Maize GDB Web site (www.maizegdb.org). Many examples are available for discussion.

Recently, Ribault and Ragot (2007) have followed the introgression of favorable alleles at five target regions in maize. Characteristics selected included increased yield, reduced water dependence, and increased synchrony between male and female flowering. Between three and four generations were needed to produce plants that recovered 85% of the parental genotype. BC₂F₃ were backcrossed to tester and then evaluated for drought resistance. When multiple hybrids were tested, the best performers increased the response to drought by 50%.

1.5 Limitations of Conventional Breeding

The product of multiple generations between the initial cross and a hybrid expressing the desired phenotype, whose parental alleles are largely preserved, is obviated by cloning. First, parent inbreds of high-performing hybrids can be altered by a single gene, thus conserving 100% of the hybrid genotypes selected through breeding. Second, it is possible to deliver single genes of commercial significance from a species totally unrelated to maize in a single transformation cycle. From a practical and economic point of view, this means that the labor-intensive, multigeneration breeding protocols needed to select for a disease-resistant phenotype are reduced, under ideal conditions, to a series of established tissue culture/transformation protocols (Sairam *et al.*, 2003). This is no small consideration given the increasing demands that have been put on alternative uses for maize, which will likely reduce its availability to its traditional markets.

1.6 Development of Transgenics

A number of cereal transgenics are available that have both social and commercial value. For example, the development of golden rice that is rich in vitamin A can combat the development of infant blindness in countries too poor to have the vitamin widely available for purchase. The development of this rice required no less than the transfer of nine different genes; a process that would have been cumbersome using traditional breeding. The production of genetically modified maize has found a number of unique economic niches. Strains of maize resistant to the European corn borer (ECB) are available for purchase. In consequence, billions of harvest dollars are saved annually in the United States (Hyde *et al.*, 1999; Wu, 2006). However, not all transgenic production is without controversy. Some issues related to yield were raised with respect to lines segregating the *Bt* gene (*Bacillus thuringiensis*). However, when incremental losses in *Bt* plants were compared to losses resulting from diseased hybrids lacking this gene, the presence of the *Bt* gene was proven to significantly increase yield (Lauer and Wedberg, 1999; Dillehay *et al.*, 2004). The efficacy of the *Bt* gene lies in the fact that the

Figure 3 Percentages of biotech and nonbiotech corn planted in the United States in 2005 [Reproduced from NCGA (2006)]

protein encoded is nontoxic to humans, animals, and honeybees (Ostlie *et al.*, 1997). The use of *Bt* corn carries with it additional social advantages, not the least of which is a reduction on the dependence of environment-challenging insecticides (Jauhar, 2001). Despite the obvious benefits of *Bt* corn, only 26% of the corn planted in the United States is genetically modified against ECB (Figure 3). Additional transgenics that have been developed for their potential economic advantages include enhanced antioxidant and essential amino acid production (Xuehui *et al.*, 2001; Dörmann, 2003) in addition to edible vaccine production (Guerrero-Andrade *et al.*, 2006).

2. GENE DISCOVERY

2.1 Introduction

The recovery of ethanol from maize starch is a first-generation technology. It has been estimated that there are 998 million dry tons of agricultural resource materials available, exclusive of an additional 368 million tons of forest resource. Regardless of the plant source, a successful ethanol biotechnology requires the ease of access to cellulose *per se* in order to solubilize hemicellulose sugars. Subsequently, cellulose is hydrolyzed to sugar, which in turn can be fermented to alcohol.

Gene discovery will make possible the designing of transgenic plants that frees cellulose from the complex polymer matrix that associates it with lignin. In principle, genes can be selected that affect some aspect of lignin biosynthesis such that either the amount synthesized and/or deposited

is reduced or the binding altered such that lignin is more easily released during biomass treatment with heat, enzymes, or acids. Once released, the cellulose itself can be hydrolyzed to its component sugars following the identification, cloning, and modification of high-performance cellulase genes and ethanol production optimized by any number of adapted genes specific to the fermentation process. A host of different protocols have been developed for maize and other plants that facilitate the isolation of genes with the expressed goal of altering some aspect of metabolism leading to the commercialization of an agri-value-added product.

The first step for transgenic maize product development is gene discovery. Gene discovery is the process of isolating a gene sequence and defining its biological function. The biological function or trait targeted for improvement in the product will determine the most optimal method used for gene discovery. In general, there are two approaches available for gene discovery: forward genetics and reverse genetics (Settles, 2005). Forward genetics starts with a phenotypic variation, most often a loss-of-function phenotype caused by a monofactorial recessive mutation, which defines the biological function of the underlying gene. For example, if the transgenic product target is earlier flowering maize varieties, then the desired gene would be one that induces or promotes flowering and whose loss-of-function phenotype is late flowering. Using forward genetic techniques, the gene sequence underlying the late flowering mutation is identified and the functional gene is used in the transgenic product. Alternatively, reverse genetics begins with a known gene sequence with a presumed relevant gene

function. Various reverse genetic techniques are employed, often relying on gene disruption, to determine the biological function of the known gene. Several forward and reverse genetic methods are available to the maize researcher for gene discovery and these are described briefly here.

2.2 Forward Genetics

2.2.1 Transposon tagging

Maize transposable elements or transposons have been used for decades for gene isolation and functional studies. Several two-component transposon families exist in maize, including the *mutator* (*Mu*), *associator/dissociator* (*Ac/Ds*) and *suppressor-mutator* (*Spm*) families, to name a few of the most often utilized (Masson *et al.*, 1991; Tacke *et al.*, 1995; Long and Coupland, 1998; Brutnell, 2002; Lisch, 2002; Kumar *et al.*, 2005; Weil, 2005). In general, insertion of the transposon into a gene disrupts its function leading to a loss-of-function mutant phenotype. Such a phenotype provides the phenotypic variation used for forward genetic gene discovery. Since the application of transposons for gene disruption and for gene isolation, also known as transposon tagging, are very similar regardless of the family of transposable element used, two different schemes for transposon tagging are described herein using the *Mu* family of elements, given that *Mu* elements have been the most successfully used family for tagging (Bensen *et al.*, 1995; Winkler and Helentjaris, 1995; Gao *et al.*, 1998; Papa *et al.*, 2001; Fu *et al.*, 2002; Dinges *et al.*, 2003; Shen *et al.*, 2003; Shi *et al.*, 2003; Carey *et al.*, 2004; da Costa e Silva *et al.*, 2004; Xiaoli *et al.*, 2004; Ada *et al.*, 2006).

Transposon tagging can be either targeted or random depending on whether the desired type of mutant phenotype already exists. If the desired type of mutation exists, then a targeted transposon tagging strategy would be used. If the desired type of mutation has not previously been identified, then a random transposon tagging strategy would be employed. For targeted transposon tagging, a reference mutation with the desired phenotype is crossed with active *Mu* lines that are wild types for the reference mutation. Again, using flowering time as our target trait, plants homozygous for a described late flowering mutation, such as *delayed*

flowering1 (*dlf1*), for example, would be crossed onto diverse active *Mu* lines that have a normal flowering phenotype (Muszynski *et al.*, 2006). *Mu* elements will transpose inserting into new genomic locations, disrupting gene function. Therefore, at low frequencies, an element will insert into the functional copy of the *dlf1* locus in the *Mu* active parent leading to a new nonfunctional *dlf1-mu* insertion allele. To uncover such an event, a large F₁ population of between 20 000 and 30 000 individuals is required, as the rate of forward mutation in active *Mu* lines varies on average from 10⁻⁴ to 10⁻⁵. The F₁ population is screened for rare individuals, which display the reference mutant phenotype; in this case, late flowering. Once identified, the rare mutant individuals are outcrossed to produce segregating families. The map position of the reference mutation must be known, as linked DNA markers are used to differentiate the reference mutant allele from the new *Mu*-insertion allele after outcrossing. Co-segregation of the new *Mu*-insertion mutant allele with *Mu* element sequences is then used to isolate the cognate gene. Targeted *Mu* tagging has been used successfully to isolate a number of maize genes affecting a variety of kernel, seedling, and adult plant traits.

Random *Mu* tagging is used if a reference mutation with the desired phenotype does not already exist. In this strategy, active *Mu* lines are outcrossed to non-*Mu* inbred lines creating F₁ seeds. F₁ plants are self-pollinated to create F₂ families, which are then screened for segregation of the desired novel mutant phenotype. Once identified, co-segregation analysis of the new *Mu*-insertion mutant allele with *Mu* element sequences can be used to isolate the cognate gene. Given the forward mutation rate of *Mu*, tens of thousands of F₂ families might need to be screened in order to identify the desired mutant phenotype. Depending on if the mutant phenotype affects kernel, seedling, or adult plant traits, this strategy may not be efficient. An alternative mutagenesis strategy utilizing chemical or radiation mutagenesis in connection with transposon tagging may be more efficient. Chemical or radiation mutagenesis methods often have a higher forward mutation rate than *Mu*. For example, ethyl methane sulfonate (EMS) mutagenesis of maize pollen can produce mutations at rates from 10⁻³ to 10⁻⁵. In addition, screening a chemically mutagenized

inbred population offers the advantage of being able to identify mutations with more subtle mutant phenotypes, as the background variation is expected to be uniform. Therefore, as an alternative strategy to random transposon tagging, random EMS mutagenesis and screening for the desired mutant phenotype can be used as a first step. After the desired mutant phenotype is identified, a targeted transposon tagging strategy can be used as previously described.

2.2.2 Positional cloning

With recent improvements in the density of markers on the maize genetic map and integration of the genetic map with the high-coverage physical map, positional or map-based gene cloning in maize is now feasible (Coe and Schaeffer, 2005; Rudenko *et al.*, 2005). The development of a complete or near complete genome sequence in *Arabidopsis* and rice has enabled positional cloning to be the standard method for gene isolation in these species. Although a complete maize genomic sequence is not yet available, efforts to sequence the maize genome are currently underway (<http://www.maizegenome.org/>). Despite this, the requisite tools for positional cloning in maize are available. In general, positional cloning relies on reiterative mapping of DNA markers, either simple sequence repeats or single-nucleotide polymorphisms (SNPs), against a segregating phenotype, typically a mutant phenotype. Co-segregation of markers linked to the mutant phenotype defines a recombination interval wherein the underlying gene is located. Reiterative mapping with evermore tightly linked markers and an ever-increasing population size defines a smaller and smaller recombination interval. Mapping is repeated until a single gene or open reading frame is identified. A review detailing the steps for positional cloning in maize has recently been published (Bortiri *et al.*, 2006). Therefore, we refer the reader to this article for information on positional cloning considerations and examples of recently map-based cloned maize genes.

2.2.3 Reverse genetics

As mentioned previously, a reverse genetics approach begins with a known gene sequence having

a presumed relevant gene function. The goal of reverse genetics is to determine or confirm the suspected gene function. This is typically accomplished by disrupting the function of the gene to produce a loss-of-function phenotype. From the nature of the mutant phenotype, one can infer a biological activity for the candidate gene. For example, disruption of the sequence homologs of the meristem identity genes *FLORICAULA* (*FLO*) from *Antirrhinum* and *LEAFY* (*LFY*) from *Arabidopsis* identified the duplicate *Zea FLO/LFY1* (*zfl1*) and *Zea FLO/LFY2* (*zfl2*) genes as the functional orthologs in maize (Bomblies *et al.*, 2003). This example highlights an important consideration when using reverse genetics. Because of gene duplication and functional redundancy, both mutated *zfl1* and *zfl2* paralogs had to be combined as a double mutant in order to display an obvious loss-of-function phenotype. Moreover, each single *zfl* mutation did display an altered phenotype but each was subtle, requiring replicated measurements and statistical analyses to detect them. Thus, reverse genetics moves from a gene to a phenotype from which gene function can be inferred. Several reverse genetic techniques have been successfully utilized and are briefly described here.

2.2.4 Trait utility system for corn (TUSC)/maize targeted mutagenesis (MTM)

Two reverse genetics methods are available, which rely on the high mutagenic activity of *Mu* transposons: the Pioneer Hi-Bred TUSC and MTM (Till *et al.*, 2003a; Henikoff *et al.*, 2004). TUSC is a proprietary collection of indexed active *Mu* x inbred F₁ DNA linked to segregating F₂ progeny seed. MTM is a similar publicly available collection of indexed F₁ DNA and F₂ progeny seed (<http://mtm.cshl.edu/>). Both collections are sufficiently large that they are expected to contain an instance of a *Mu* insertion in every gene in the maize genome. Both collections are used in the same manner. For each candidate gene of interest (GOI), both forward and reverse polymerase chain reaction (PCR) primers are designed to specifically amplify defined regions of the candidate GOI. Each forward and reverse primer is paired with a degenerate primer designed from the consensus *Mu* terminal inverted repeat (TIR) sequence in

PCR amplification reactions. Thus, gene-specific primer and *Mu*-TIR primer amplifications are performed on the complete F₁ indexed DNA collection, with appropriate controls. Amplification of a gene-primer + *Mu*-primer product identifies an F₁ plant that carried a *Mu* insertion in the candidate GOI locus. Sequencing the amplification product will identify the exact insertion site of the *Mu* element in the genomic sequence and will aid downstream analysis. The F₂ progeny seed from the identified F₁ DNA sample is obtained, grown, and observed for segregation of any mutant phenotype(s). Characterization of additional independent *Mu*-insertion alleles and co-segregation analysis will confirm the suspected biological function of the candidate GOI. Several maize genes, homologous to genes from other plant species, have been confirmed to mediate the same biological function or have identified novel functions. As mentioned earlier, due to extensive duplication of the maize genome, gene redundancy is often an issue with any reverse genetics approach.

2.2.5 Targeting induced local lesions in genomes (TILLING)

Another reverse genetics tool available to the maize community is TILLING (Till *et al.*, 2003b, 2004; Weil *et al.*, 2005). TILLING relies on the high forward mutation rate of EMS mutagenesis and the ability to detect the resultant transversions or transitions as SNPs in PCR amplification products. First established for use in *Arabidopsis*, it has now been adapted as a maize functional genomic tool (<http://genome.purdue.edu/maizetilling/>) (Singh *et al.*, 2003; Kolkman *et al.*, 2005). TILLING is done in a manner similar to TUSC/MTM. Candidate GOI-specific primers are used to query a collection of DNA from a mutagenized population for loss-of- or altered-function alleles. Different algorithms aid in the positioning and design of PCR primers, aimed to optimize identification of nucleotide changes that would impact gene activity. Once different point-mutation alleles are identified, the corresponding F₂ or F₃ families are grown. Analysis of F₂ or F₃ families for a mutant phenotype that co-segregates with the new EMS allele will determine gene function.

2.2.6 Mapped activator

Recently, a reverse genetics method utilizing the tendency of *Activator* (*Ac*) transposable elements to insert into linked sites has been developed (Brutnell, 2002; Cigan *et al.*, 2005; McGinnis *et al.*, 2005). Regional mutagenesis utilizing *Activator* in maize (http://bti.cornell.edu/Brutnell_lab2/Projects/Tagging/BMGG_pro_tagging.html) aims to place an active *Ac* element every 10 cM (centi-Morgans) throughout the maize genome. The system relies on the tendency of *Ac* to transpose to linked sites combined with a reporter allele, which indicates *Ac* dosage. The map position of the candidate GOI must be known in order to choose the closest linked *Ac* line with which to initiate the mutagenesis screen. In brief, the mapped *Ac* line linked closest to the GOI is outcrossed to the reporter allele line. Kernels with a transposed *Ac* are selected, based on their increase in *Ac* dosage, and grown. PCR screening with GOI-specific and *Ac* termini-specific primers will indicate if the newly transposed *Ac* has inserted in or near the GOI. Plants carrying an *Ac* insertion in or near the GOI are self-pollinated producing segregating families. Families are observed for an altered phenotype co-segregating with the *Ac*-insertion allele, thereby confirming gene function. Although primarily used as a reverse genetics tool, the mapped *Ac* lines can also be used for targeted transposon tagging using a reference mutation that maps within 10 cM of a mapped *Ac*. While still being developed, this technique provides the maize community with another functional genomics tool for gene discovery and functional analysis.

2.3 Verification

Once a gene has been identified and assigned a biological function, the next step in product development is to verify that modulation of the gene's expression in transgenic maize plants does indeed affect expression of the target trait in a desirable and predictable manner. Modulation of gene expression is typically done using one of the following three methods: gene overexpression, gene silencing, or gene shuffling. The method of expression modulation depends on the nature of the gene's endogenous expression and the desired phenotype of the product. For example, to

produce early flowering in maize, overexpression of a floral induction gene, like *dlf1*, would be tested in different transgenic constructs by driving expression of *dlf1* with constitutive promoters of varying strengths. Once a method of expression modulation is selected, the next step is to generate a sufficiently large number of events of each construct to adequately evaluate their efficacy. This step is dependent on having an efficient and high-capacity transformation system. Moreover, transformation in an inbred background facilitates phenotype screening in either inbred or hybrid backgrounds. The final step in verification is to develop and apply suitable molecular and phenotypic assays to ensure that the construct meets acceptable efficacy criteria to warrant its advancement through the product development process. Each of these steps is discussed in more detail below.

2.3.1 Modulate gene expression

Modulation of gene activity for product development involves gene overexpression, gene silencing, or gene shuffling. Each produces a new dominant trait to be incorporated into a commercialized product. Overexpression produces more of a gene product, usually in additional tissues and for a longer period of time than the endogenous gene. Typical constitutive promoters, such as *ubiquitin* or *actin*, are used, although there are many other choices available. Additionally, constitutive promoters of differential strengths—mediating high, medium, or low expression levels—are tested to determine an optimal degree of regulation. Gene silencing is another method used to modulate gene expression and serves to down-regulate or terminate gene activity. This can be achieved by several methods. Typical silencing constructs rely on inverted or direct repeats to create double-stranded hairpin transcripts of coding or promoter sequences. Other silencing strategies use RNA interference (RNAi), antisense RNA (asRNA), or small interfering RNA (siRNA) approaches, to name a few (Waterhouse *et al.*, 1998; Boubakri *et al.*, 2006; Hecky *et al.*, 2007). The third method of expression modulation is gene shuffling. Gene shuffling is a process of *in vivo* mutagenesis and selection for altered or novel protein activity (i.e., increased thermotolerance, altered enzyme

specificity, or improved kinetics). The process for gene shuffling is well described (Castle *et al.*, 2004; Pattanaik *et al.*, 2006). Shuffled genes are usually selected in microbes, such as bacteria or yeast, as this facilitates the automation and screening of sufficiently large and complex shuffled libraries. Gene shuffling has only recently been applied to agricultural improvement, as there are inherent limitations with selection *in planta* at each round of shuffling. Even so, some success has been reported. Once an appropriate method for gene expression modulation is determined, the resultant promoter–gene combination is constructed and maize transformants are generated.

3. PLANT TISSUE CULTURE AND TRANSFORMATION

3.1 Introduction

The development of robust plant regeneration protocols from single cells capable of being transformed at high frequency that combines speed, output, genotype independence, and host genome stability has been long recognized as the holy grail of plant biotechnology. In order to meet this goal, many different explants have been tested for their regeneration capacity. These include shoot apices, leaf and stem segments, hypocotyls, epicotyls, immature embryos, and mature intact seed. Regeneration of cells derived from these explants has been attempted and achieved through manipulation of a number of developmental pathways. Plants can be regenerated by multiplying preexisting shoot meristems, by direct shoot morphogenesis, and indirectly and/or directly from undifferentiated cells, such as those associated callus and through somatic embryogenesis (Thorpe, 1994).

Historically, the development of plant tissue culture, especially in the cereals, developed independently of any associated transformation endeavors. Indeed, the first transformation attempts by Coe and Sarkar (1966) attempted to produce genetically modified pollen following treatment of the developing tassel with DNA in solution. In consequence, as new transformation technologies were developed for tobacco, these were tested in turn for their applicability with respect to the cereals. Hence, in the early days of

cereal biotechnology, tissue culture development and transformation did not develop in parallel.

Different transformation systems have been tested on maize cells. These include the direct DNA uptake technologies embracing polyethylene glycol (PEG) Ca^{++} enhancing, silicone carbide whiskers, microinjection, and electroporation-mediated nucleic acid transfer. The conspicuous advantage of these technologies in aggregate is that DNA delivery is genotype independent. However, in order to be used at all, totipotent protoplasts must be available for transformation across a wide variety of genotypes within a given species. This has yet to be achieved. Biolistics is also a direct transfer technology whose use is protoplast independent but whose maximal utility requires genotype-independent regeneration. The use of *Agrobacterium tumefaciens*-mediated transformation requires suitability of host range and that the genetically modified cells are regenerable following infection.

This section summarizes the major advances that have been made toward the production of maize transgenics. In particular, it will be argued that the community is positioned to produce, in large numbers, transgenic cereals independent of genotype (Sairam *et al.*, 2002, 2003; Al-Abed *et al.*, 2006) and whose commercial limitations will be a function of the cloned genes available for exploitation and commercialization. Finally, the most recent progress in this lab using the newly reported split-seed technology is reviewed: a tissue culture procedure from which 50 plants can be regenerated from a single seed, each originating from a single shoot bud.

3.2 Explants Used for Maize Regeneration and Transformation

Minimally, there are four requirements needed to produce a transformation protocol that have equal utility in academia and industry. First, those cells targeted for DNA uptake must be capable of regenerating fertile plants. Second, regeneration should be genotype independent, particularly with respect to inbred lines. Third, regeneration should be rapid, producing large numbers of plants arising from either single cells or shoot buds. Finally, the system should be user friendly, minimizing growth chamber space, greenhouse footprint area,

and labor. In the following sections, the different explants are reviewed that have been tested for regeneration and transformation in maize and have been evaluated according to these criteria.

3.2.1 Immature embryos

Immature embryos have been extensively used for maize regeneration and transformation since the first report on the establishment of totipotent callus from which maize plants regenerated (Green and Phillips, 1975). Plant regeneration from immature embryos can be obtained by somatic embryogenesis and organogenesis. In the case of somatic embryogenesis, callus is induced from immature embryos and with further culturing the callus becomes embryogenic and produces somatic embryos, which in turn germinate to produce a complete plant with a shoot and root. In organogenesis, the shoots are either directly induced from embryos or directly regenerated from callus (Springer *et al.*, 1979; Lu *et al.*, 1982; Lowe *et al.*, 1985; Vasil *et al.*, 1985). Thus, the utility of this explant depends upon a readily available supply of embryos that commits greenhouse space to this effort. This dedication can be significant; especially if a large number of inbreds are being tested for their suitability in the production of transgenic hybrids.

The callus from maize cultures is mainly classified into three types. Nonembryogenic callus is watery, usually turns brown and loses its ability to regenerate and therefore is unsuitable either for propagation or transformation. Type I embryogenic callus is usually compact and white in color and plants can be regenerated directly through organogenesis. Unfortunately, the utility of this type of callus is diminished as it cannot be maintained for long periods of time. Type II embryogenic callus is friable, soft, and yellowish (Green *et al.*, 1983).

Both types of embryogenic callus are mostly induced from the middle and the coleorhizal end of the scutellum (Lu *et al.*, 1982; Vasil *et al.*, 1985). Immature embryos of 1–2 mm size were found to be the optimal for induction of embryogenic callus (Green and Phillips, 1975). The regeneration process is primarily divided into three stages. The embryos are cultured on either modified MS (Murashige and Skoog, 1962) or N6 (Chu

et al., 1975) medium supplemented with 2,4-dichlorophenoxyacetic acid (2,4-D) and incubated in the dark at 26–28 °C for callus induction. The embryogenic callus is then transferred to media containing 2,4-D and transferred to the dark, thus allowing the maturation and germination of somatic embryos. Alternatively, the cultures may be returned to the light and cultured on a medium lacking 2,4-D. Under these conditions, regeneration from direct organogenesis occurs.

The use of immature embryos as a starting point for the development of transgenic maize, indeed for any plant, comes at a price. There are technical problems to consider. These include strict limitations with respect to the size and stage of embryo used (Armstrong, 1994), genotype restrictions (Tomes and Smith, 1985; Horn *et al.*, 2006), and somaclonal variation and albinism (Armstrong and Phillips, 1988). In addition to these limitations and those related to greenhouse space, the establishment of accountable embryogenic suspension cultures requires a minimum of 1 year, to say nothing of the continuous, labor-intensive maintenance (Bhaskaran and Smith, 1990). Then, too, the recovery of fertile plants, either from protoplasts or from the embryos themselves, can likewise take an additional 9 to 12 months. Hence, either universities or companies seeking to employ this labor-intensive technology must be prepared to invest a minimum of 2 years before the first transgenic seed is harvested.

Immature embryo-based regeneration systems have proven to be effective for the genetic transformation of maize. Nearly 15 years passed between Green and Phillips' (1975) initial report of regeneration using immature embryos and the first report of fertile transgenic plants obtained from embryogenic suspension cultures derived from immature embryos (Gordon-Kamm *et al.*, 1990). Different methods have been used to transform immature embryos. These include particle bombardment, electroporation, *Agrobacterium*-mediated transformation, and whiskers-mediated transformation (D'Halluin *et al.*, 1992; Ishida *et al.*, 1996; Songstad *et al.*, 1996; Petolino *et al.*, 2000). These different transformation methods report a wide frequency of transformation efficiencies ranging from 0.8% to 45% (Wright *et al.*, 2001; Zhao *et al.*, 2001).

Given the wide range of transformation frequencies and the number of methods by which

DNA can be transferred either to embryogenic tissue or protoplasts, the choice of delivery remains an issue. There have been a stunning number of improvements made in the last 15 years that especially adapt *Agrobacterium* for use in maize. Among these has been the development of the supervirulent strains (Hood *et al.*, 1993) wherein multiple copies of specific genes of the *vir* regulon have been introduced into the bacterium resulting in heightened rates of T-DNA transfer. Accompanying the increase in transfer is low copy integration, thus insuring simple Mendelian transmission while eliminating gene silencing associated with multiple integrative events (Shou *et al.*, 2004). The numerous improvements associated with *Agrobacterium* have proven most effective using the inbred A188 and its derived hybrid progenies such as Hi-II (Frame *et al.*, 2006; Hiei *et al.*, 2006; Horn *et al.*, 2006).

Depending on the maize line and how it is manipulated prior to DNA transformation, certain cultivars may prove refractory to *Agrobacterium* infection, and hence alternative delivery strategies must be employed. Following biolistic treatment or whisker-mediated transformation of either embryogenic callus or cell suspension cultures, transgenic plants may be regenerated. Lowe *et al.* (1995) also reported transformation of shoot apices but progeny were not obtained. It was concluded that further manipulations were needed to overcome this problem. A number of reviews are available for particle bombardment and *Agrobacterium*-mediated transformation discussing the different parameters to consider in using each method (Taylor and Fauquet, 2002; Cheng *et al.*, 2004).

3.2.2 Embryogenic cell suspension cultures

Embryogenic cell suspension cultures for maize cells are initiated from type II friable callus derived from immature embryos (Vasil and Vasil, 1986). To initiate a suspension, fresh soft embryogenic callus is dispersed in liquid MS or N6 media supplemented with 2,4-D, and cultures are kept in shaker in dark for a period of 4 to 6 months with routine subculturing and adding fresh media every 3–4 days till they can be used for transformation. The establishment and the regeneration process of cell suspension culture are well described by

Vasil and Vasil (1986). Cell suspension cultures were successfully used for obtaining transgenic plants by particle bombardment and whisker-mediated transformation (Gordon-Kamm *et al.*, 1990; Frame *et al.*, 1994).

The advantage of using the cell suspension cultures lies in the ability to maintain the cultures for a long time (cryopreservation) when time is a critical factor especially for industrial production of medicinal compounds. In addition, cell suspension cultures are the only source for the isolation of maize protoplast that can be regenerated to plant (Vasil and Vasil, 1986). Most importantly, cell suspension cultures are the only source for the isolation of maize protoplasts capable of regeneration (Vasil and Vasil, 1986).

3.2.3 Protoplasts

In principle, protoplasts are attractive targets not only for gene delivery but also for regeneration. Maize regeneration from isolated protoplasts using type II callus was first reported by Rhodes *et al.* (1988). The resulting plants lacked utility as these were sterile. Shortly after this initial report, fertile maize, derived from protoplasts, was regenerated (Prioli and Söndahl, 1989; Shillito *et al.*, 1989). Competent protoplasts are maximized following 9 months of subculture of the original mother culture (Shillito *et al.*, 1989). In order to generate protoplasts, suspension culture cells are added to a mixture of cellulose degrading enzymes. After cell wall degradation, the protoplasts are harvested, stabilized on an MS medium containing high molar sucrose, centrifuged, washed with salt solution, and resuspended in protoplast culture media (Shillito *et al.*, 1989). The protoplasts are then plated on a layer of nurse cells derived from the original suspension culture seeded beneath filter paper to allow division and proliferation. The protoplast-derived embryogenic callus is then cultured on MS media supplemented with cytokinins, and regeneration occurs. The utility of this technology is genotype specific and hence limited.

Since protoplasts lack a wall, this cell population is amenable to transformation by direct DNA uptake. Methods include electroporation, PEG-mediated transformation, and Agrolistic

transformation (Fromm *et al.*, 1986; Armstrong *et al.*, 1990; Hansen *et al.*, 1997). Despite all of the intensive activity using protoplasts, their utility as a generator of fertile plants remains limited (Golovkin *et al.*, 1993). Indeed, when protoplast-mediated transgenic plant technology is evaluated as a whole, the number of fertile engineered plants produced remains unalterably low. When this limited output is considered against the labor-intensive activities associated with their fabrication, the cost-benefit ratio is minimally suspect. In reality, the recent advances in transformation methodology that produce transgenics in greater numbers and at faster speeds using a wider range of genotypes argue that the routine use of protoplasts serves no particular advantage.

3.2.4 Explants from mature seeds

Given the restrictions associated with protoplast usage and despite reports testing immature embryos derived from numerous maize inbreds and hybrids, routine production of transgenic plants from commercial cultivars remains limited using these starting materials (Horn *et al.*, 2006). In recent years, researchers have shifted focus and are testing tissues derived from mature seed for regeneration and transformation (Zhong *et al.*, 1992; Li *et al.*, 2002; Sairam *et al.*, 2002, 2003; Al-Abed *et al.*, 2006). In one approach, the apical meristems are dissected following germination and cultured on MS media supplemented with cytokinins to induce multiple shoots (Gould *et al.*, 1991; Zhong *et al.*, 1992). The process of plant regeneration from shoot meristems mainly consists of three steps: induction, multiplication, and elongation of shoot buds, resulting in mature plant development in the greenhouse.

Excised shoot apical meristems have also proven to be efficient explants for maize transformation using either particle bombardment or *Agrobacterium*-mediated transformation (Gould *et al.*, 1991; Zhong *et al.*, 1996; Zhang *et al.*, 2002). Congruent with apex excision are reports of chimeric transformants (Zhong *et al.*, 1996). However, Sticklen and Oraby (2005) have pointed out that chimerism of transgenic plants can be avoided when transformed meristems are multiplied for 2–3 months.

Alternatively, Sairam *et al.* (2003) have shown that a multiplicity of shoots can be proliferated from complete maize meristems following incubation on a germination medium containing 2,4-D. If these meristems are in turn subcultured in the light on a modified MS medium containing 6-benzylaminopurine, six to eight shoots are produced per meristem, independent of all genotypes tested. Seed was recovered in 6 to 9 months from the original time of explant implantation. If the meristems are placed in the dark and cultured on a modified MS medium containing 2,4-D, somatic embryogenesis is formed and fertile plants are subsequently recovered yielding harvestable seed in 6 to 9 months. Albinos and plant chimeras are notably absent using this procedure.

This technology also holds great promise for recovering transgenics in large numbers following *Agrobacterium*-mediated transformation. If the maize seeds are germinated on a medium containing auxin, 60–86% of shoot meristems show uniform transient expression of either β -glucuronidase (GUS) or green fluorescent protein (GFP) across the entire surface of each explant. This observation was confirmed following PCR analysis and the GFP marker segregated in a 1:1 ratio in the pollen. The high transfer rates were independent of the use of supervirulent *Agrobacterium* strains provided the seed was first germinated on auxin-supplemented, modified MS media.

Huang and Wei (2004) have reported regeneration of plants through callus initiation from mature embryos. The embryos were sliced and cultured on N6 media supplemented with 2,4-D and induced callus was further cultured on media containing cytokinin and silver nitrate. The number of regenerated shoots per callus, however, was small, i.e., two shoots. A more recent report from Sidorov *et al.* (2006) showed that nodal sections of 7- to 10-day-old maize seedlings can be transformed with *Agrobacterium* and subsequent transgenic plants were regenerated from type I callus. Whether this system continues to be explored depends upon the extension of the totipotency of type I callus, to say nothing of increasing the shoot output.

Most recently, the utility of “split seeds” as a novel explant has been explored by Al-Abed *et al.* (2006). By splitting the seed longitudinally,

three different tissues containing meristematic cells are exposed simultaneously. These tissues include the scutellum, coleoptilar ring, and shoot apical meristem (Figure 4). Split-seed explants from the inbred lines R23 and B73 and the hybrids Hi-II and LH198 x LH227 were tested for regeneration output. An average regeneration frequency of 76% is observed, and in each explant expressing regeneration the mean number of shoots regenerated is 28 (Figure 5). Hence, potentially, more than 50 plants can be rapidly produced per seed. Fertile seed can be recovered in 6 months from split-seed implantation. Finally, based on electron microscopy analysis, each plant has been shown to be originated from a single shoot bud (Figure 6). Since plant production is high, conditions are currently being optimized that will link high-frequency DNA transfer to this robust regeneration protocol.

Indeed split-seed explants have been successfully used to introduce the *Arabidopsis CBF3* gene under the control of the inducible promoter rd29A by particle bombardment (Al-Abed *et al.*, under review). The stable integration of the *CBF3* gene has been confirmed in T₀ and subsequent generations (Figure 7). The performance of these maize transgenics is currently being evaluated under conditions of abiotic stress. Finally, with the continuing perfection of the split-seed technology, it should be possible to automate this process, thus allowing its rapid production of value-added transgenics while reducing the dependence on the need for labor and space.

3.3 Transformation

A high-efficiency, high-capacity transformation system is necessary to generate a sufficient number of primary transformants (T_0) for efficacy testing. Typically, upward of 20 to 30 primary transformants are made to adequately test a construct. Additionally, 3 to 8 different constructs may be tested for a given gene. Therefore, 60 to 240 T_0 must be generated to adequately assess a reasonable number of constructs. Although transformation with the “gene gun” or biolistic methods is common, transformation mediated by *Agrobacterium tumefaciens* is the method of choice today. As described below, recent evidence suggests

that shoot meristems and “split seeds” may be ideal explants for inbred transformation using *Agrobacterium* when competence is primed using a modified MS medium supplemented with auxin (Figure 8). Not only is the rate of transfer DNA (T-DNA) transfer high but none of the genotypes tested have proven refractory to regeneration by either somatic embryogenesis or direct organogenesis (Sairam *et al.*, 2002, 2003; Al-Abed *et al.*, 2006).

3.4 Optimization

The next step in product development is to optimize the transgenic construct. This step

Figure 6 Microscopy images of embryogenic callus and initiating shoot buds: (a) embryogenic callus showing meristematic cells on the peripheral sides; (b) actively dividing cells; (c–e) scanning electron microscope of meristematic cells grouping to form shoot buds [Reproduced from Al-Abed *et al.* (2006). © Springer]

usually requires (1) testing alternative promoters to produce an optimal expression level and degree of phenotypic change, (2) choosing suitable selectable markers, (3) evaluation of phenotypic expression, and (4) event sorting, where a large number of events are tested to obtain the most efficacious and

stable insertion. Optimization requires expanding field evaluations to test additional constructs effectively and to determine commercially acceptable levels of phenotype improvement and stability without a deficit in any other agronomic trait.

3.4.1 Promoter testing

Once an efficacious promoter–gene combination has been identified from the verification stage, alternate promoters are tested to achieve a commercially acceptable change in the target trait.

One of the originally tested promoters may be sufficient but typically testing several different promoters is required. Alternative promoters may mediate different levels of constitutive expression, may restrict expression temporally and/or spatially, or may be inducible. The choice

of promoters to test depends on the target trait and strategy for modification in the product. Early and rigorous field testing is also required to determine the most optimal promoter–gene combination for product advancement.

3.4.2 Selectable markers

Selectable and screenable marker genes are key factors in discriminating between putative transformants and unaltered plants. Most of the selectable markers that have been used in maize transformation are genes that give resistance to antibiotics or to herbicides (Spencer *et al.*, 1990; Walters *et al.*, 1992). Some of the concerns related to public acceptance and the chance of environmental contaminations from using those types of marker genes have led the industry to focus on eliminating these genes while replacing them with more environmentally friendly markers that can potentially contaminate any rung in the food chain. An example is the use of the phosphomannose isomerase gene (*PMI*) (Wright *et al.*, 2001). A list of selectable marker genes used in maize transformation along with their respective promoters is summarized in Table 1. The use of a specific promoter is determined by whether expression is to be constitutive, as when selecting for initial transient expression in the target cell, or selective with respect to tissue and/or timing.

3.4.3 Evaluation of phenotypic expression in transformants

After generating a sufficient number of transformants for each construct, construct efficacy, or the ability of the construct to mediate the desired change in the target phenotype, is evaluated. In order to efficiently evaluate a construct, several molecular and phenotypic assays are developed that determine if a construct is mediating the desired phenotype to an acceptable degree. Usually, a number of criteria must be met or exceeded to allow a construct to move to the next stage or phase of product development. Although the types of assays are particular to the trait targeted, there are a few standard metrics that must be met. Analysis of the primary transformant or T₀ plant is desirable, as this will allow only events meeting the criteria to advance to field testing. Molecular assays to assess the number and fidelity of integration of the transgene construct in each T₀ event are conducted. Also, quantitative expression analyses are needed to confirm that the transgene transcript is present and accumulates to the expected level in the correct tissue. Additional expression analysis of the protein may also be performed. Minimally, one should identify intact, single-copy transgene integration events that produce detectable full-length transcript. T₀ events meeting these criteria are pollinated to produce a segregating family for field testing. Back crossing the inbred T₀ to the same inbred will produce a T₁ family segregating 1:1 for the presence or absence of the transgene for each event. Alternatively, crossing to an unrelated or heterotic inbred will produce segregating T₁ hybrids for field evaluations.

There are many options for the degree and rigor of the initial field evaluation. Determination of the essential objectives at this stage will help to decide the types of measurements, number of replications, level of detection of effect, and statistical design of the field evaluation. Most often, the primary limiting factor for T₁ field evaluations is the amount of T₁ seed produced. Typical T₀ plants yield only a few hundred kernels, half of which are azygous for the transgene. Therefore, highly replicated destructive measurements are precluded in first-generation field evaluations. The main objective of T₁ field evaluations is usually to determine if 50% or more of the events within a

construct are mediating a measurable or detectable change in the target trait or component of the trait in the transgene-containing plants compared to their nontransgenic sibs or other controls. The degree of change may not be what is needed for a commercial product but this issue is addressed in the optimization stage. A primary verification goal is to identify constructs that are having no effect or a detrimental effect on plant performance. Such constructs are filtered out, which allows more resources to be directed to fewer efficacious constructs. Once efficacious constructs and events are identified, seed increases at the T₂ stage allow for more rigorous field testing. Results from replicated, multiyear, multilocation field tests produce enough empirical outcomes to warrant advancing a construct. At the conclusion of the verification stage, a promoter–gene combination that mediates a detectable, predicted change in the target trait is identified. Once this is achieved, the construct advances to the optimization stage of product development.

3.4.4 Event sorting

After the most optimal promoter–gene construct has been identified, a very large number of transgenic events must be generated. Typically 100 or more events of the optimized construct are generated and evaluated in replicated field tests. At this stage, position effects of the transgene are being evaluated. Local genomic position influences the amount and stability of expression. Event sorting for stable and optimal expressivity and penetrance of the transgenic phenotype through several generations occurs at this step. A high-capacity, efficient transformation system and ample field testing resources are needed at this stage. The effect of different growing environments can also be assessed on the optimized event(s) by testing in different locations. This helps determine the stability of the phenotype in different geographic locations.

3.5 Regulatory Rules for Transgenic Maize

The United States Department of Agriculture Animal and Plant Health Inspection Service (APHIS) have strict rules regulating the release

and planting of transgenic plants. These have been summarized by Ellstrand (2003). Plants producing any industrial/chemical products now come under regulation. Indeed, APHIS has taken great pains to protect the public from the possibility of nontransgenic seed being contaminated with transgenic seed. In consequence, perimeter fallow zones are required. Moreover, the planting of food and field crops at the same location in subsequent seasons is prohibited in order to avoid contamination by volunteers. Farm implements must be dedicated either for use with transgenics or nontransgenics. This includes both planting and harvesting equipment in addition to prescribed storage depots. Both machine and personnel training programs are mandated for all workers coming in contact with transgenic seeds.

With respect to producing pharmaceutical active compounds in corn, the regulations are particularly strict. APHIS requires that no other corn be grown within 1.6 km if the transgenics being field tested are open pollinated. If controlled pollinations are made by placing pollen bags on top of the tassels, no other corn can be grown within 800 m. Moreover, if the transgenic corn in question expresses a pharmaceutical product, then the planting must be time staggered. This corn must be planted either 28 days before or after any other and in a zone enforced between 800 and 1600 m of the test site.

4. COMMERCIALIZATION

4.1 Introduction

The final stage in transgene product development is commercialization. At this stage, the best optimized events are either backcrossed or retransformed into elite germplasm in order to produce competitive hybrids with the new or improved trait. In addition, the new transgene trait is stacked with other genetically modified (GM) or native traits into a total product “package” carrying all of the trait improvements offered to the customer. Finally, the total package of improved traits is tested across diverse geographies under standard grower’s input and tested for trait improvement and high yield. Typically, only the top one or two events are advanced to this stage. Integrating or backcrossing the trait into

current elite inbreds is expensive and must be done quickly, as elite inbreds are usually replaced by superior inbreds every 5 to 10 years. Alternatively, once the top event is introgressed into a few key inbreds, it can be incorporated into the breeding germplasm for development and selection of new inbreds. Doing so raises regulatory issues, as all inbred development and testing would need to be regulated as GM material. However, this is the current practice for soybeans and will likely be the future for maize breeding as well. As the number of improved GM and native traits increases, the number of combinations of these traits into potential products increases exponentially. Most will be combined together as a “stacked” product package with several GM and native improvements to a single hybrid. Different GM traits may be combined at one or a few transgene integration sites or possibly carried on artificial chromosomes. Selection for improved native traits with markers (marker-assisted selection, MAS) can be done during the integration of the transgene into elite inbreds. Stacked products are tested in comparison with standard and competitor hybrids for improved trait performance and hybrid yield across geographies. Hybrids with superior yield and improved traits are advanced for commercial production and sale to farmers to meet the ever-growing need for food, feed, and biorenewable materials.

4.2 Stress Tolerance

The *Arabidopsis* transcriptional factor *DREB1A/CBF3* under the control of the inducible R29a promoter has been successfully transformed in maize (2007Al-Abed *et al.*, under review). Corn expressing *CBF3* gene showed significant tolerance to cold, drought, and salinity compared to wild-type plants. In the case of maize, segregating *CBF3* can be grown for weeks at 10 °C with no ill effects and can survive below freezing. Indeed, more than 60% of the corn survives under drought conditions of 21 days and under conditions of 400 mM salt. The availability of these genes and others that confer resistance to biotic stressors will have the effect of increasing the acreage under corn cultivation, thus providing more seed. This is no small consideration given that seed is likely to be diverted from its traditional commercial uses

to a market place allowing higher profit margins for farmers. In this connection, maize bioreactor pharmaceutical production and ethanol synthesis are but two of the markets to which maize seed is likely to be redirected. The availability of these genes and others that confer resistant biotic stressors will have the effect of increasing the growing range of corn.

4.3 Vaccines and Antibodies

Collectively, the pharmaceutical industry must be prepared to accept the inevitable pressure of designing new production designs that will reduce drug costs to consumers, especially in developing countries. Today, state-of-the-art production of genetically engineered proteins is done in mammalian cell culture. A minimum investment of 100 million dollars is needed to build a factory that will produce them, depending on the product-limited quantity.

Moreover, the use of mammalian cell culture as bioreactors for production of human interest proteins (HIPs) carries with it certain intrinsic health risks. Specifically, there is an inherent danger of viral contamination associated with mammalian-derived materials that necessitates exhaustive safety testing and validation of production processes. Animals infected with certain zoonotic viruses have transmitted fatal illnesses to humans. Numerous mouse-derived cell lines are known to contain endogenous retroviruses and some demonstrate species-specific tumorigenic potential. Oncogenic xenotropic murine retroviruses are of particular concern because of the many theoretical risks they present to humans. New viruses with altered pathogenicity or host range could be generated through genetic recombination. Tumors also may form through integration of the viral genome in close proximity to a host oncogene, thus activating the oncogene.

Within the plant biotechnology sector, there is a great interest in expressing mammalian proteins in plants in a way that would allow their commercial exploitation. The advantages of producing therapeutic recombinant proteins in plants are many. These include the ability to fabricate HIP on an agricultural scale, thus lowering manufacturing costs significantly, and the ability, for example, to export highly sought and needed therapeutic

proteins that remain stable in dry seed for extended periods of time. HIPs cover a broad range of commercially important, value-added products, which include vaccines, antibodies, hormones, peptides, cytokines, enzymes, and bioactive lipids. Most importantly, no human or animal pathogens have ever been reported that infect plants. Thus viral contamination that is observed in animal cell culture is absent in plants.

Transgenic plants have been produced that express a number of different HIP molecules using a variety of plant species (Mason and Amtzen, 1995; Arakawa *et al.*, 1998; Mor *et al.*, 1998, 2001; Zeitlin *et al.*, 1998). In maize, the B-subunit of heat-labile enterotoxin has been produced (Lamphear *et al.*, 2002). Enterotoxigenic *Escherichia coli* (ETEC) is the leading cause of diarrhea in children under the age of 5 in third-world nations. ETEC pathology is profound and results in 650 million cases of diarrhea that kills 800 000 children annually (Black, 1986). The ability to translate the expression of the B-subunit and proteins like it into edible vaccine will likely figure prominently into the commercialization of maize transgenic seed.

Monoclonal antibody production should likewise do the same. Recently, Meristem Therapeutics has announced the expression of IgA1 in maize. The protein made has been shown to regress tumors in lungs, breasts, and pancreases of model animals. Large amounts of antibodies are needed equal to several grams/day/patient. Since 200 monoclonal antibodies are in trial, an additional 600 are in the preclinical phase. The utility of a storage vessel like maize seed coupled with abundance is likely to create a bioreactor of choice in the future.

4.4 Ethanol

The fuel ethanol industry is the second largest user of corn grain in the United States following livestock feed. Twenty percent of domestic corn was fermented into fuel ethanol in 2006 (USDA, 2007). While the process technology has existed in the past century (Bothast and Schlicher, 2005), the industry has experienced unprecedented growth over the past 5 years, with the annual production capacity in the United States more than doubling to over 5 billion gallons (Figure 9). An additional

Figure 9 Growth of ethanol production in the United States (RFA, 2007)

3.4 billion gallons of capacity are currently under construction (RFA, 2007).

This growth has been propelled by three primary drivers. (1) Refiners uniformly switched from methyl tert-butyl ether (MTBE) to ethanol as a fuel additive to meet the octane and emission requirements for reformulated gasoline set by the 1990 Clean Air Act Amendments. While MTBE had been banned in over 20 states because of concerns over drinking water contamination, the complete changeover occurred following the Energy Policy Act of 2005 (EPACT, 2005), which did not include a liability waiver protecting refiners against future MTBE contamination lawsuits. (2) Federal incentives for ethanol production include an excise tax credit of \$0.51/gallon ethanol awarded to blenders for using ethanol in gasoline and a \$0.10/gallon income tax credit for small-scale ethanol producers (defined as producers making less than 60 Mgal/year and limited to \$1.5 million annually). Many states offer additional incentives for ethanol production while some provide rebates for purchasing vehicles equipped with fuel flexible engines that enable operation on high ethanol content blends (RFA, 2007). (3) Technology maturation has decreased the cost of producing ethanol while high petroleum costs have driven up its selling price resulting in large profits for ethanol producers.

Legislation has played a key role in influencing demand and will continue to do so as researchers have highlighted its positive impact on energy security, environmental performance, and rural development. Corn-derived ethanol is a renewable, domestically available fuel that can reduce the

country's dependence on imports of foreign petroleum (Farrell *et al.*, 2006). Moreover, since ethanol produced in the United States is primarily based on corn, the carbon dioxide emitted during combustion was originally taken up by the corn plant during growth. Therefore, ethanol utilization plays a role in lowering domestic greenhouse gas emissions. Increased ethanol production also contributes to the rural economy by boosting corn prices and creating jobs for construction and manufacturing (Swenson, 2005). For these reasons, EPACT 2005 initiated the development of a Renewable Fuel Standard that requires a minimum of 7.5 billion gallons per year in renewable fuel production by 2012 (EPACT, 2005). With the call by President Bush to replace 75% of petroleum imports from the Middle East by 2025 (State of the Union Address January 31, 2006), many policy makers and groups have called for further legislation to greatly expand the minimum fuel production.

4.4.1 Process descriptions

Over 95% of ethanol produced in the United States is made from corn (RFA, 2007). However, the production processes vary considerably and desirable output traits will be dependent upon the mode of processing. Thus, to properly size the market for a given trait, the specific process and economic benefit that the trait targets must first be quantified.

Corn grain is fermented into ethanol through two primary pathways: the wet mill and the dry grind processes. Historically, large corn processors have built wet mills as they have the flexibility to produce a portfolio of different products including high fructose corn syrup, corn gluten feed, corn germ, corn oil, and others in addition to ethanol. Wet mills operate similarly to a petroleum refinery as they can optimize output depending on market conditions, but they are also much more capital and energy intensive. By contrast, dry mills are optimized for ethanol production and therefore they are considerably less expensive and more efficient, albeit less flexible. Most of the increase in capacity over the past decade has been supplied by dry mills. Other feedstocks, such as milo and wheat starch, can be used in processes similar to the dry grind. It is expected that lignocellulosic

biomass will be used for ethanol production in the future. As corn stover is a potential feedstock for the cellulosic process, this process is also described below.

4.4.2 Wet mill process (EPA, 1995)

In the wet mill process (Figure 10), delivered and screened corn grain is initially steeped in dilute sulfur dioxide to degrade the protein in the grain and remove the soluble fractions. The steep water from this first step passes through multieffect evaporators to recover the protein, which can be sold as feed supplements. The steeped corn continues through mills that strip out the germ and some of the starch and fiber. The germ is removed from the pulp using a liquid cyclone and the oil is extracted to be sold as a product. The remaining corn flows through more washes, screens, and mills to separate out the bran, which is combined with the spent germ from the oil extraction and sold as corn gluten feed. At this point, the primary corn grain stream now consists mostly of the gluten and starch. The next step is a centrifugation stage where corn gluten meal, a high-protein (60–70%) animal feed, is produced. The starch and residual gluten and solubles are then processed downstream into starches, sugars, high fructose corn syrup, ethanol, or other fermentation products. For ethanol production, the process of converting the starch is very similar to the dry mill process described below.

4.4.3 Dry mill process (Kwiatkowski *et al.*, 2006)

In the dry grind process (Figure 11), the delivered corn grain is screened and ground in a hammer mill. The ground corn is mixed with thermostable α -amylase enzyme, ammonia, lime, and water in a slurry tank for the liquefaction step. A jet cooker is used to inject steam into the process to begin gelatinization where the starch is hydrolyzed into oligosaccharides. The liquefaction conditions are typically 88 °C, pH 6.5, with a residence time of 1 h. After liquefaction, the mash is cooked in a downstream tank for 15 min at 110 °C before being cooled down to 60 °C for the saccharification step. During saccharification, glucoamylase enzyme is

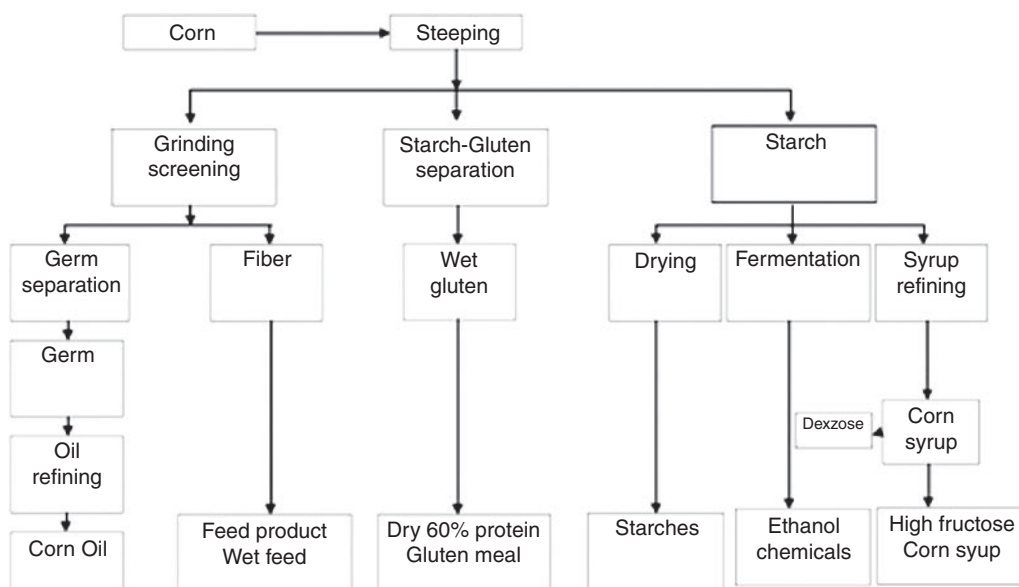

Figure 10 Process flow diagram for the wet mill process [Reproduced from RFA (2007)]

added to the slurry to further hydrolyze the oligosaccharides into their component glucose sugars. Sulfuric acid is added to lower the pH to 4.5 during the 6 h required for saccharification. After saccharification, the slurry is cooled again to 32 °C for the fermentation. Yeast is added during fermentation to convert the sugars into ethanol

and carbon dioxide in large fermentation tanks. The tanks are continuously cooled and mixed using the compressed off gas carbon dioxide, which contributes to pH control. Typical residence times for the fermentation range from 36 to 72 h. The outlet beer has an ethanol content of about 10% (w/w).

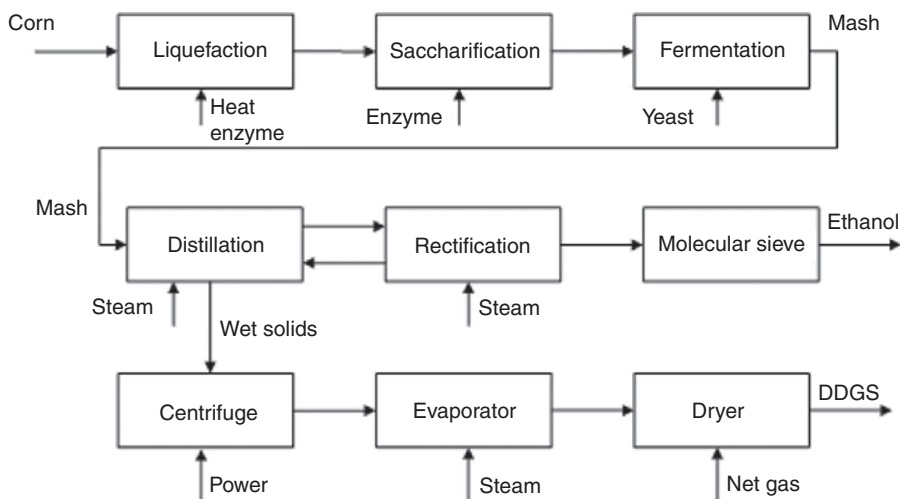

Figure 11 Process flow diagram for the dry grind process

The beer stream is fed to a steam reboiled distillation column where the ethanol purification begins. In the beer column, nearly all of the ethanol and most of the water is separated from the unfermented proteins, oil, fibers, and byproduct chemicals. The top of the beer column contains the ethanol/water mixture and this stream continues on through another distillation, a two-step rectification/stripping process before final dehydration in a molecular sieve. The stillage or “bottom” fraction from the beer column, containing the unfermented proteins, oil, fibers, and byproducts, is dewatered using a centrifuge and then dried further in a series of evaporators before final drying in a drum dryer. The final product from the drum dryer is called distiller’s dried grain and solubles (DDGS), which can be sold as animal feed.

A variation of the dry mill process is the raw starch process (Wang *et al.*, 2005). In a raw starch dry mill, the high-temperature liquefaction is replaced with a low-temperature operation that requires significantly more glucoamylase enzyme. The increase in enzyme offsets the elimination of the gelatinization step, which is normally used to improve the liquefaction efficiency. The primary advantage of raw starch processing is a reduction in capital and energy costs.

4.5 Cellulosic Ethanol (Aden *et al.*, 2002)

Ethanol can also be produced from lignocellulosic biomass. While this process has not been demonstrated on a commercial scale, many believe that it is the most promising alternative ethanol process because of the wide availability of inexpensive cellulosic feedstock. This process may become valuable for corn producers because corn stover, the stalks, leaves, and cobs, are a cellulosic feedstock that could be collected and converted into ethanol. The actual process has many of the same steps as the dry grind process but there are slight differences.

In cellulosic ethanol processing (Figure 12), the corn stover is delivered to a processing facility where the material is degraded into sugars and then fermented into ethanol. The corn stover is initially milled and treated with dilute sulfuric acid and high temperature steam in the pretreatment and hydrolysis stage. These initial reactions break apart the cellulose–hemicellulose–lignin matrix into a hemicellulose hydrolyzate along with the remaining cellulose and lignin. Because this step is performed at extreme conditions, the material requirements for the reactor can lead to exorbitant costs. The hydrolyzate stream is filtered of the solids and treated in a detoxification step where

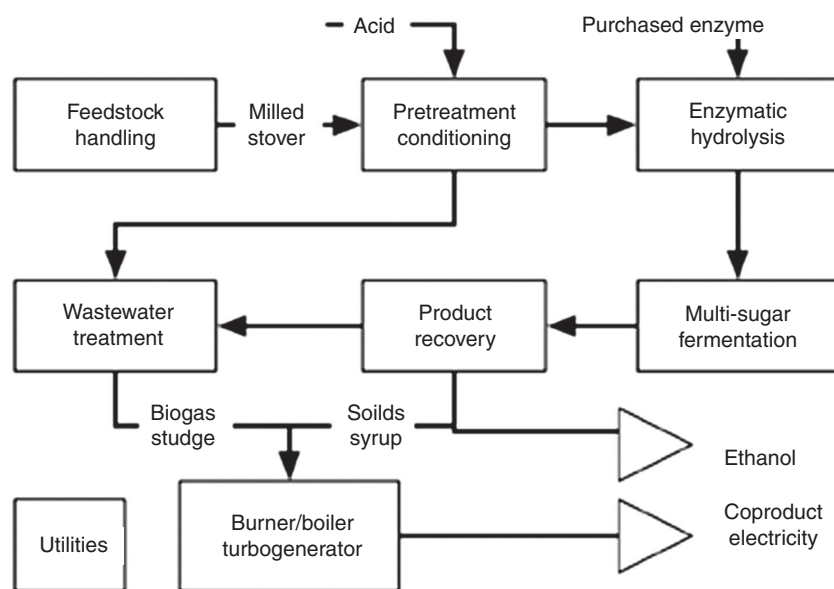

Figure 12 Process flow diagram for the cellulosic ethanol process [Reproduced from Sheehan (2003)]

lime is added to neutralize the remaining acid with gypsum as the waste product. The liquid stream is then recombined with the solids from pretreatment and pumped to the saccharification reactor where enzymes are added. These enzymes hydrolyze the cellulose into its component glucose sugars. The saccharification is performed in cascading tanks and is followed by fermentation tanks, where both the glucose and the pentose sugars from the hemicellulose are converted to ethanol. The ethanol is purified using a process similar to the dry and wet mill processes. Solids from the initial distillation are separated and dried using a centrifuge and evaporators before being combusted for steam production and power generation for the processing facility. Excess electricity can be sold to the grid as a co-product.

The cellulosic ethanol process can have several variations. The most typical difference is in the pretreatment and hydrolysis processes. While the description above highlights the dilute acid pretreatment followed by enzymatic hydrolysis, a number of other technologies are being investigated. Examples of other processes are concentrated acid hydrolysis, hot water pretreatment, and ammonia explosion pretreatment (Mosier *et al.*, 2005). The process of breaking open the biomass to liberate the sugars is both technically and economically challenging, so developing a process that more closely follows the dry mill liquefaction process is important.

4.6 Ethanol Process Economics

The wet mill and dry grind processes are relatively mature and while opportunities to optimize both exist, economic viability relies primarily on the commodity prices of the corn grain, ethanol, and various co-products. Conversely, the cellulosic process remains uncommercialized and significant process development is required for large-scale deployment. Short descriptions of the economic performance are given here for the dry mill and the cellulosic process as these are likely to provide the majority of current and future industry growth.

The ethanol production costs for the dry mill process can be roughly divided into five categories: corn, energy, other raw materials and utilities, fixed costs, and capital costs, with revenue from co-product DDGS being a negative cost.

Table 2 Example production costs for the dry mill process^(a)

Inputs	\$/gallon EtOH
Shelled corn	1.02
Natural gas	0.13
Electricity	0.03
Other raw materials, utilities	0.12
Labor, supplies and overheads	0.12
Capital charges	0.13
DDGS credit	−0.24
Total costs	1.32

^(a)Source: Tiffany and Eidman, 2003; Kwiatkowski *et al.*, 2006

Based on studies investigating the economics of dry mill processing (Tiffany and Eidman, 2003; Kwiatkowski *et al.*, 2006), the production cost ranges from \$1.00–\$1.50/gallon of ethanol and is highly dependent upon corn grain prices. Table 2 gives an example of these relative costs and shows that the two largest cost contributors are the corn grain and the DDGS. Moreover, the prices for these two commodities are impacted directly by increased ethanol production, with higher demand for corn leading to higher prices and a larger supply of DDGS leading to lower prices. Both of these changes have negative impacts on the ethanol production costs.

The growth of the industry in the first decade of the 2000s significantly impacted corn utilization. Corn grain used for ethanol production increased to a market share of 20% of the total US corn production (USDA, 2007). With continued expansion, the ability to supply enough corn grain may become constrained. Late in 2006, competition for corn from the livestock and ethanol industries had driven the price of the grain to unusually high levels (USDA, 2007).

Increased dry grind ethanol production also impacts the supply of DDGS. The co-product can partially displace corn demand as a feed alternative; however, this replacement is limited by DDGS nutritional composition and transportation challenges. Ethanol industry growth of the 2000s led to a potential oversupply of DDGS and drop in DDGS prices, which decreases corn ethanol profit margins. This was demonstrated during the late 2006 surge in corn prices as DDGS, typically sold at a premium to corn in ruminant markets, began to be priced at a discount to corn (Lohrmann, 2006). These two economic parameters, the price of corn and the price of

DDGS, will have a considerable impact on the future ability for ethanol producers to operate a profitable enterprise.

Other factors influence the economics of dry mill processing to a lesser degree. The overall conversion of corn grain to ethanol is important; however, with mature processing technology, most new facilities achieve a conversion of 2.75 gallons of ethanol per bushel of corn, which is over 95% of the theoretical limit and leaves little room for conversion improvement. Opportunities for reduced energy utilization include lower temperature liquefaction, improved ethanol/water separation technology, and decreased drying requirements for the co-product DDGS. Moreover, while ethanol producers primarily use natural gas for energy, alternative fuels such as coal, waste biomass, and methane gas from anaerobic digestion have been used to lower energy costs. Maximizing the energy utilization efficiency of the process and finding inexpensive energy sources will remain a critical aspect of the economics. Capital and operating costs are important as well, but because of the rush to build new facilities and relative maturity of the process technology, new technologies are being implemented slowly. In fact, the capital costs for dry grind manufacturing facilities increased during the ethanol boom in the early 2000s as demand for engineering, construction, and materials led to premium costs.

4.7 Opportunities for Improved Ethanol Production Using Transgenic Technology

Many opportunities exist for biotechnology to improve the economics of ethanol production. Bothast and Schlicher (2005) list the following priorities: new feed stocks and co-products; fermentation, saccharification, and hydrolysis improvements; fiber and germ recovery; DDGS optimization; and distillation and other separations optimization. New trait development can have a positive impact in all of these improvement areas; however, biotechnology improvements not based on plant traits will not be discussed here. New traits are a valuable tool for expanding corn production and ensuring crop harvest, both of which help maintain an adequate supply of grain at affordable prices for ethanol production.

Input traits have the potential to decrease ethanol processing costs indirectly by enabling the harvest of an adequate supply of corn grain that meets both ethanol and feed requirements at competitive prices. Traits focused on yield, pest resistance, herbicide resistance, and stress tolerance all affect the available corn supply and thus the price of corn grain. For example, pest-resistant corn helps protect the crop from infestation, which on average should increase the yield per acre versus pest susceptible corn. Transgenic yield improvements also would indirectly benefit the economics of ethanol production and complement breeding improvements. Additionally, new traits, such as cold, salinity, drought, and other stress tolerance, enable expanded production by allowing farmers to grow corn in less ideal soils and climates.

The processing of the corn grain to ethanol can be improved with a number of different transgenic output traits. An example is the development of breeds of corn with higher starch and fermentable sugar content, which would be beneficial for both wet and dry mill processes, assuming that the cost of fermentable sugar on a mass basis decreases. An increase in the available sugars for fermentation could increase the theoretical maximum of 2.85 gallons of ethanol per bushel of corn to a higher value, thereby decreasing the per gallon raw material cost. Initial work by Monsanto and Pioneer has resulted in the development of “Processor Preferred Fermentable Corn” and “High Total Fermentables” ethanol optimized varieties (Bothast and Schlicher, 2005). While these products have been developed using traditional breeding, compositional changes, such as increased starch content, can be accomplished by modifying genes that impact the synthesis, degradation, and accumulation of starch in plants. Further modifications to the starch composition of the corn grain could change the ratio of amylase and amylopectin, which affects the degradation and viscosity properties of the starch.

Other genetic modifications can underlie output traits that impact the efficiency of various unit operations in the ethanol process. A primary example is the amylase corn developed by Syngenta, which produces α -amylase enzyme in the endosperm of the corn kernel (Singh *et al.*, 2006). The thermostable enzyme increases its activity in the presence of water and elevated temperature, enabling the hydrolysis of starch

into oligosaccharides. This corn variety has been developed for the dry mill industry and decreases the requirement for addition of exogenous α -amylase enzyme; thus lowering the raw material costs for the ethanol production. The same corn could be used in the raw starch process variation to decrease α -amylase requirements and expanded to include thermostable glucoamylase enzymes embedded within the corn grain. Providing both enzymes within the corn may eliminate the need for exogenous enzyme while enabling low-temperature processing that can reduce capital and operating expenses. The cost savings enabled by using corn that produces its own enzyme are estimated to be between \$0.03–\$0.07/gallon for the dry mill process. This modest estimate (from 2% to 7% of dry mill processing costs) may be expanded in the raw starch process, where eliminating the jet cooker and high-temperature liquefaction and consolidating the saccharification could provide a saving of approximately \$0.20/gallon or more if fewer inhibitory compounds or the level of maillard products were produced.

The nonfermentable segment of the corn grain consists of fiber and protein, a byproduct that is sold as animal feed. While a number of technologies have been developed to separate out the other subcomponents of the corn kernel, such as germ and oil, or to convert the fiber into additional ethanol, the remaining protein could be augmented with additional modifications to the corn to increase its value. Possibilities are the modification of the protein or amino acid composition and the addition of other nutrients or embedding enzymes such as phytase, which are added into the animal feed downstream. Depending upon the specific modification, increasing the value of the DDGS stream (which currently provides an approximately \$0.15–\$0.25/gallon credit) can have a large impact on the ethanol cost structure.

4.8 Enabling Cellulosic Ethanol

The most significant opportunity for increasing ethanol production from corn is by enabling the utilization of the stover and fiber as feedstock. Similar compositional modifications and processing capabilities can be applied to corn stover for

improved cellulosic ethanol production as were described for corn grain ethanol production.

There is significant potential for producing ethanol from lignocellulosic materials such as corn stover, and research in this area has become a major focal point for the US Department of Energy (DOE) and United States Department of Agriculture (USDA). Thus far, commercial production has been limited to a couple of small-scale pilot plants and demonstration facilities because of the expensive processing costs (DOE, 2006b). The economics of cellulosic ethanol production are considerably different than that of the dry mill process, with the cost per gallon estimates ranging from \$1.50 to \$2.20 using current technologies (Aden *et al.*, 2002; DOE, 2006b). The primary advantage of cellulosic ethanol production is the lower feedstock costs provided by corn stover and other biomass materials; however, this advantage is overcome by increased processing costs. The recalcitrance of the lignocellulose requires a severe pretreatment and an adequate supply of enzymes is much greater than the dry mill process leading to exorbitant capital and operating costs.

Many of the same transgenic opportunities described above for starch processing can also be utilized for enabling the production of ethanol from corn stover. The production of plant structural components, including lignin, hemicellulose, and cellulose, can be altered to increase the polysaccharide content and lower the lignin content. Such changes in cell wall biochemistry would provide greater levels of sugar in a form that could be processed more easily. Unfortunately, cell wall biosynthesis and the mechanisms of pretreatment reactions and cell wall degradation are still not well-understood phenomena. Preliminary annotation of the *Arabidopsis* genome has identified at least 1000 known or putative genes encoding cell wall related proteins (Yong *et al.*, 2005). Among the targets currently studied are genes in the cellulose synthase family (*CESA*), cellulose synthaselike (*CSL*), xyloglucan endotransglycosylases/hydrolases (*XTH*), expansins (*EXPA*, *EXPB*), expansinlike (*EXLA*, *EXLB*), p-Coumarate co-enzyme A ligase (*CCL*) and endoglucanases or plant-produced cellulases (Cosgrove, 2005).

The cost advantages of optimized compositional modifications are hard to predict. For example, while decreasing lignin composition may improve

ethanol production costs by decreasing the pretreatment conditions (resulting in up to a \$0.20/gallon cost reduction and importantly decreasing the upfront capital requirements for processing facilities) and decreasing enzyme requirements (estimated at \$0.15–\$0.50/gallon), it may also reduce the lignin available for energy generation, which is a valuable byproduct (providing \$0.10–\$0.25/gallon for energy purchase offsets and electricity credits). Compositional modification may also enable process improvements in purification or allow higher sugar streams to be used, which would decrease capital costs. However, until plants are actually made with these modifications and their processing capabilities are tested, it is unclear what the economic impact will be. Furthermore, if compositional modifications to corn affect agronomic performance, the plant is unlikely to be commercially viable and may have difficulties progressing through the regulatory process. While compositional modifications can be identified in traditional breeding programs and some have been studied in depth (e.g., the maize brown mid-rib mutants), so far none have found widespread commercial use and have not yet enabled cellulosic ethanol production.

Similar to the improvements made by amylase production for grain ethanol facilities, improvements in cellulosic ethanol processing can be expected from plant production of cellulase, hemicellulase, and ligase enzymes. From a cost perspective, these enzymes are responsible for \$0.15–\$0.35/gallon but in a mature cellulosic ethanol market are likely to be in high demand, which could drive enzyme costs higher. Consider that 0.020 g cellulase/g cellulose is required for the process and if cellulase production is approximately 100 g/l, then the fermentation capacity required for enzyme production for a 30 billion gallons cellulosic ethanol market would be 17.6 billion gallons, which creates a severe problem, considering the amount of glucose that will be required to support enzyme production at this scale.

Producing the cellulase enzymes in plants may enable low-cost cellulosic processing, saving enzyme costs, and potentially reducing the pretreatment requirements. One of the concerns of this option is that the enzymes may become active and hinder normal plant growth. To date, most studies expressing cellulase enzymes in plants have investigated the plant as a

source of enzymes, as opposed to creating a low-cost processing trait. Despite the difference in experimental objective, the production of unmodified lignocellulosic degrading enzymes has previously been demonstrated (Dai *et al.*, 1999; Ziegelhoffer *et al.*, 1999) and some studies showing high-protein expression have also been associated with hindered crop growth (Hood *et al.*, 2003; Clough *et al.*, 2006). Other studies have been performed with reportedly normal plant growth but these have shown low enzyme expression, have used enzyme catalytic domains lacking a binding domain, or have been performed in a less relevant model system than corn (Dai *et al.*, 2000a, b, 2005). None of these referenced reports have demonstrated the ability to produce multiple cell wall degrading enzymes in the same plant, which is known to have a synergistic effect on the activity of cell wall degrading enzymes (Wood and McCrea, 1986; Wood *et al.*, 1986; Woodward, 1991; Mansfield *et al.*, 1999). Additionally, studies conducted thus far have yet to challenge the plants at temperatures where the enzymes are active. The lack of a relevant temperature challenge is important because some enzymes may become active in the field, thus threatening harvest yields and agronomic performance, which is a critical consideration for maize traits. Finally, the targeting of the enzymes within cells or organelles has been practiced as an approach to ensure proper maturation of the plants (Jin *et al.*, 2003). This approach limits the enzyme accumulation potential, does not work for all enzymes (Hood *et al.*, 2003; Clough *et al.*, 2006), and distances the enzyme from its substrate providing a lower impact on the pretreatment costs.

While producing processing enzymes in the plant can have a dramatic impact on cellulosic ethanol production costs (estimated at between \$0.15/gallon and over \$0.65/gallon), obtaining high enough enzyme levels that still allow normal plant maturation and do not interfere with agronomic performance is critical. One solution often practiced is the use of thermophilic enzymes, whose activity is decreased at moderate temperatures and increased at high temperatures. While the activity modulation may be adequate to avoid adverse effects on plant physiology, this requires high-temperature processing, which prevents further process optimization that may occur at lower temperatures. Mechanisms that

control plant enzyme activity *in vivo* would be valuable to producing lignocellulosic degrading enzymes, and other enzymes in plants.

Given the rapid expansion in ethanol production over the last 5 years and the projected continued expansion over the next 5 to 20 years, agricultural biotechnology promises to have a strong impact on ethanol processing costs. Unlike improvements in single unit operations, transgenic traits have the potential to affect every unit of operation from the field to the final product. Input traits can impact yield and ensure availability, which ultimately affects the cost of sugar used in the ethanol fermentation. Output traits can change the cost structure of any targeted unit operation. Traits such as compositional modification and enzyme expression, depending upon the affected processing steps, could ultimately decrease the cost of producing cellulosic ethanol by over 35% using today's technology as a baseline.

In this review, the status of maize biotechnology has been reviewed and its likely impact on energy production evaluated. In 2004, 11% of the corn harvest produced 3.4 billion gallons of ethanol (DOE, 2006a). This volume supplies but 1.7% of the nation's fuel demand. Nevertheless, this output was sufficient to generate 147 000 that translated into \$2 billion of additional tax revenue.

If corn remains the principal engine of ethanol production in this country, then an unhealthy competition ensues between its utility as a food, feed and manufacturing additive, and as an energy source. In recent years, corn has dipped below \$2.00/bushel when purchased for its traditional use and is expected to bring more than \$4.00/bushel when purchased for ethanol production. In order to solve this problem, new technology needs to be developed that taps into a significant portion of the more than 1.3 billion dry metric tons of agricultural resources available whose ethanol is produced from cellulose. The cost to fund the laboratories that will provide impetus for gene discovery, for isolation of genetic regulatory elements that specify the time and tissue in which gene expression occurs, the delivery of newly synthesized heterologous genes to produce the transgenics, and their subsequent evaluation, to say nothing of the bulking of seed material, is high. However, if one considers that in 2005, more than \$250 billion was spent on oil imports, perhaps the investment in the development of cellulosic biotechnology is indeed a bargain.

5. CONCLUSION

In this review, an attempt has been made to provide an overview of the advances in maize biotechnology that involve from a concept to product development. In the last 10 years maize tissue culture has advanced to the point where it is robust with respect to speed and to the number of regenerants per explant. Most important are the observations that suggest that cell regeneration competence can be induced, making the procedure genotype independent. Of equal importance is the fact that the cells capable of regeneration are likewise competent with respect to gene transfer. Complementing the development of linked regeneration/DNA transfer protocols are the vigorous gene discovery programs. In principle, now any gene should be transferable making it possible to produce a large number of commercially available corn hybrids. These have been produced after many generations of selection and breeding, and now the technology exists to make them transgenic by the addition of single genes to the parental inbreds.

Hence with an investment that is small relative to potential economic recovery transgenic maize can be readily produced that range from its capacity to grow in alternative environments to serving as a bioreactor. It is likely in fact that maize because of the seed's large storage capacity will be used to produce a wide range of HIPs to service drug delivery in those parts of the world that are too poor to establish an alternative infrastructure. Then too the capacity to make transgenic maize to grow in a wide variety of environmental challenges will stabilize food resources as corn is shunted into the production of biofuel. Because of its importance, globally transgenic maize is a tool for good and will remain so in the hands of all who are of good will.

Wheat

Paramjit Khurana, Harsh Chauhan and Shreenivas A. Desai

Department of Plant Molecular Biology, University of Delhi, New Delhi, India

1. INTRODUCTION

Global population growth in the next 50 years would occur essentially in the developing countries where malnutrition is already prevalent and over 800 million people face daily hunger. Forty percent of the world's land use for agriculture is already seriously degraded and to meet the nutritional needs of this growing population, cereal production in general and wheat production in particular will need to be increased by 40% in the next 20 years. Wheat is one of the world's most important food grains that provides more than 20% of the calories and protein in human diet, and the staple food for over 40 countries, accounting for 35% of the world's population (Bushuk, 1998). It is thus alarming to note that since 2002, world wheat stocks have declined gradually from 237 to 174 million tons in 2006 (FAO, 2006). Therefore, increases in wheat productivity in a sustainable way using conventional breeding methods anchor its limitations. A biotechnological tool for sustainable food supply is needed to meet these requirements in the near future.

1.1 Wheat Improvement

From its first introduction in 1996 till date, genetically modified (GM) crops have been adopted by more than 8.5 million farmers in 21 countries covering around 400 million hectares of cultivated land. Remarkably, the global biotech crop area increased by more than 50-fold in the

first decade of commercialization of GM crops. However, wheat is still not part of GM crops grown in the field (International Service for the Acquisition of Agri-biotech Applications, 2005). Wheat grain yield is a complex trait, reflecting the culmination of vegetative and reproductive growth and development, and their interactions with the edaphic and aerial environments. Stably expressed genes leading to higher grain yield are important targets of wheat breeding. Quantitative genetics now offers the prospect of dissecting and characterizing the genetic complexity of yield. Moreover, the coincidence of quantitative trait loci (QTL) for yield and those for other traits provides information on traits likely to be responsible for yield. Recently, Uauy *et al.* (2006) reported the positional cloning of *Gpc-B1*, a wheat QTL associated with increased grain protein, zinc, and iron content. The ancestral wild wheat allele encodes a NAC transcription factor (*NAM-B1*) that accelerates senescence and increases nutrient remobilization from leaves to developing grains, whereas modern varieties carry a nonfunctional *NAM-B1* allele.

Increasing grain yield can be achieved by increasing either the total biomass produced by the crop or the proportion of the total biomass that is invested in grains (greater harvest index). Grain yield also represents the product of grain number and mean weight per grain. Grain number *per se* can be broken down into its components: ear number per plant and grain number per ear, which are determined by the number of spikelets per ear and grains per spikelet. Therefore, by studying how

these yield components vary within a particular genetic background, it is possible to gain an insight into the possible function of a gene that influences yield and when, as well as how, they are likely to exert the effect(s).

1.2 Need for Genetic Engineering of Wheat

One of the major limitations in conventional breeding involves the barriers for gene transfer through incompatibility and species differences. Progress in biotechnology has resulted in insertion of desired foreign gene(s) to overcome problems of sexual incompatibility and species barriers between organisms. This technology helps breeders and molecular biologists to introduce the gene of interest with more selective modification and represents a significant advance. In addition, transgenics have many other advantages, namely, the potential to resist biotic and abiotic stresses, add nutritional quality to the product, herbicide and pesticides resistance, etc., resulting in increased productivity. Recent genetic engineering technology allows not only transfer of a single gene, but also a couple of genes in a much more precise, controllable, and predictable way than is achievable with conventional breeding. Genetic engineering offers a useful supplement to plant breeding like the killing protein (KP4) from maize has been transferred to wheat (Clausen *et al.*, 2000) for imparting resistance against stinky smut (*Tilletia tritici*) and similarly a potent antimicrobial protein Ace-AMP1 from onion (*Allium cepa*) was transferred for enhancing fungal disease resistance (Roy-Barman *et al.*, 2006). Improvements can thus be achieved in much shorter time frames and of selected traits.

2. DEVELOPMENT OF TRANSGENIC WHEAT

2.1 Technical Advances in Wheat Transformation

2.1.1 Particle bombardment mediated transformation

The majority of wheat transformation investigations reported (Vasil *et al.*, 1992, 1993; Weeks *et al.*, 1993; Becker *et al.*, 1994; Nehra *et al.*,

1994; Zhou *et al.*, 1995; Altpeter *et al.*, 1996; Barro *et al.*, 1997; Zhang *et al.*, 2000; Melchiorre *et al.*, 2002; Chugh and Khurana, 2003; Patnaik and Khurana, 2003; Yao *et al.*, 2006) have utilized microparticle bombardment technology for wheat transformation.

Vasil *et al.* (1991, 1992) for the first time stably transformed wheat suspension cells and callus lines through particle bombardment. However, from suspension cells regeneration could not be achieved and regenerated plants from the callus lines were sterile. Perl *et al.* (1992) reported that for bombardment the regeneration of scutellar calli can be rendered efficient and the time required considerably accelerated by a liquid culture phase. The expression of reporter gene following DNA delivery can be improved by maintaining the scutellar calli in 0.25 M mannitol before and after bombardment, by bombardment in the presence of silver thiosulfate and $\text{Ca}(\text{NO}_3)_2$ (rather than CaCl_2) and by the elimination of spermidine from the DNA/microparticle mixture. A protocol that includes all these features leads to several-fold higher transient expression of the reporter gene.

Weeks *et al.* (1993) for the first time reported production of fertile transgenic wheat through particle gun by using 5-day-precultured immature embryo of 0.5–1.0 mm size. The frequency was, however, very low as 1–2 transgenic plants could be recovered out of the 1000 explants bombarded. Moreover, it takes around 5–6 months to seed setting of T_0 plants according to the protocol followed by them. In a similar study by Becker *et al.* (1994), particle bombardment was done with pDB1 plasmid in scutellar tissue. They also optimized several parameters such as distance between different gun components, gas pressure, partial amount of vacuum, and size and amount of particles per bombardment. Around 100 transient transformation events per embryo could be observed. However, after selection on Basta, 12 plants were recovered out of 1050 bombarded explants. Nevertheless, the transgenics obtained showed Mendelian inheritance for the genes introduced.

Takumi and Shimada (1997) studied the genotypic influence on regeneration and transformation. They used six genotypes in the study and found that although transient gene expression was similar among the genotypes, recovery of stably transformed plants varied significantly. The better

responding genotypes, namely, Akadurama and Norin 12, showed 1.4% and 1.7% transformation frequency, respectively, but no transgenic plants were recovered. This was attributed to their *in vitro* culture response variability rather than the transformation procedure. Similarly, Ingram *et al.* (1999) optimized parameters for transient gene expression in microspore-derived embryos of wheat. A preculture of 4 h in 0.4 M maltose was found to enhance the transient expression by a magnitude of 3.

One of the major drawbacks of particle bombardment-mediated genetic transformation is the integration of multiple copies of the transgene. Srivastava *et al.* (1999) demonstrated a possible way to obtain single copy transgenics based on site-specific recombination of the *cre-lox* systems (Sauer, 1994). They designed a plasmid pVS11 harboring *bar* gene flanked by *lox* recombination sites and thus four multiple copy loci were resolved successfully into single copy transgenes.

In a subsequent work by Pastori *et al.* (2001), two elite wheat varieties were transformed with a relatively high embryogenic capacity by particle bombardment. A strong correlation between transformation frequency and the age of wheat donor plants was observed in both varieties. The mean transformation frequency increased from 0.7% to 5% when using immature embryos from old and young donor plants, respectively. The efficiency of biolistic transformation strongly depends on the condition of the donor plant and the plant genotype chosen for the transformation process. Pellegrineschi *et al.* (2002) analyzed the transformation efficiency of 129 wheat sister lines. Of the 129 genotypes evaluated, 8 demonstrated transformation efficiencies above 60% (60 independent transgenic events per 100 immature embryos bombarded). Bobwhite SH 98 26 was identified as a supertransformable wheat line. Recently, Yao *et al.* (2006) reported low copy gene transfer but stable expression of transgene in a commercial wheat via particle-gun method. They made linear gene constructs lacking vector backbone and containing a promoter, ORF, and terminator. Despite the transformation frequency was low, being 0.5–0.6% only, the expression of transgene *1Ax1* (coding for a unit of HMW glutenin) was conformed in the T₁ progeny by sodium dodecyl sulfate polyacrylamide gel electrophoresis and reverse transcription polymerase chain reaction (RT-PCR) analysis.

2.1.2 *Agrobacterium*-mediated transformation of wheat

Agrobacterium-mediated transformation has several desirable features over naked DNA delivery, such as introduction of few copies of genes and more chances of recovery of single copy transgene, high co-expression of introduced genes, easy manipulation of transgene and the ability to transfer large segments of DNA with minimal rearrangements, and lower cost of experimentation (Hiei *et al.*, 1994; Gheysen *et al.*, 1998; Hansen and Wright, 1999; Shibata and Liu, 2000; Jones *et al.*, 2005). Though several attempts were made to transform cereal crops with *Agrobacterium* as early as in 1988 by Grimsley *et al.* (1988), the first rice transformation was reported by Raineri *et al.* (1990). Stable wheat transformation through *Agrobacterium* could only be achieved in 1997 (see Table 1), when Cheng *et al.* (1997) successfully transformed a variety of wheat explants with a transformation frequency ranging from 0.14% to 4.3%. They studied several factors affecting transformation frequency, such as explant type (leaf tissue from young seedling, immature inflorescence, freshly isolated and precultured immature embryos, embryogenic callus derived from immature embryos, and cells in suspension culture), *Agrobacterium* cell density for inoculation, inoculation and co-cultivation time period, co-culture medium and presence of surfactant and inducer in the inoculation medium. However, they did not use any gene of interest but inheritance and expression of *nptII* and *uidA* genes were analyzed till T₂ generation, and in most of the transgenic events the transgenes behaved as dominant loci exhibiting normal Mendelian segregation with 98% co-expression as determined by paromomycin leaf paint and β -glucuronidase (GUS) histochemical assay. Nevertheless, presence of inducer acetosyringone and glucose in the inoculation and in co-cultivation medium was necessary for freshly isolated immature embryo transformation, while these could be omitted for transformation of suspension culture cells suggesting differing competence of various explants for *Agrobacterium*.

As an alternative explant, Amoah *et al.* (2001) used immature inflorescence from a commercial wheat cultivar of spring wheat, Baldus, known for its hard endosperm and bread making quality. They took 0.5–1.0 cm immature inflorescence and precultured them on media containing

Picloram and AgNO_3 . *Agrobacterium* hyper virulent strain AGL1 with plasmid pAL156 and pAL186 were used for transformation by liquid media inoculation, as well as by sonication and vacuum infiltration. Presence of acetosyringone (200 μM) in inoculation and co-cultivation media was necessary as no GUS spots were visible in the absence on the same. Moreover, acetosyringone was found to be effective in a dose-dependent and time-scale manner. A lower concentration (100 μM) can be complimented by longer time inoculation and vice versa, while a higher concentration of acetosyringone (400 μM) was found to be less responsive and somewhat bacteriostatic in action. Another factor influencing transient gene expression was the time of preculture, i.e., time between when inflorescence was first isolated and cultured to when the explants were incubated with *Agrobacterium*. A period of 21-day preculture was most responsive (76% GUS expression) but, 7-day preculture is necessary for GUS expression (if any). Preculture length beyond 21 days resulted in decrease in the number of explants showing *uidA* expression. A similar trend was observed in *uidA* expression in terms of number of spots per explant. In the line of other workers, Amoah *et al.* (2001) found a bacterial density of $A_{660} = 1.5$ most responsive. They also found beneficial effects of vacuum infiltration of *Agrobacterium* during inoculation both in terms of explants showing *uidA* expression as well as spots per responding explants. In a separate experiment, sonication was done for different time periods (2–6 s) during inoculation and positive effect was seen in terms of explants producing GUS expression, but number of spots per explants reduced as compared to the control.

Wu *et al.* (2003) studied and optimized factors affecting transfer-DNA (T-DNA) delivery and regeneration, namely, embryo size and duration of preculture, inoculation, co-cultivation, and presence of acetosyringone and Silwett L-77 in the media for two winter and two spring wheat genotypes. Among all the genotypes tested, embryo size of 1.5 mm was found to be best responsive in terms of GUS expression. However, the response in tissue culture showed opposite trend with the smaller size calli showing significantly higher regeneration frequency. In accordance with previous studies (Cheng *et al.*, 1997; Amoah *et al.*, 2001), presence of acetosyringone (200 μM) enhanced GUS expression significantly, both in

terms of percent explant showing GUS expression as well as spots per explant. Contrary to the study carried out with immature inflorescence by Amoah *et al.* (2001) where longer preculture (21 days) enhanced transformation frequency, a reverse phenomenon was observed by Wu *et al.* (2003) in their study. Transformation efficiency reduced greatly even if explants were precultured for more than 1 h.

In an augmented approach toward overcoming the recalcitrance for transformation and regeneration in commercial wheat genotypes, Khanna and Daggard (2003) used super binary vector carrying extra set of *vir* genes for transformation of Australian spring wheat genotype “veery 5.” *Agrobacterium* strain LBA4404 with super binary vector pHK21 and binary vector pHK22 were used. They found that normal binary vector pHK22 when used gave no transient GUS expression in 587 3-week-old calli, while super binary vector pHK21 gave 17 stable transgenic plants out of 658 calli used in agroinfection. To gain maximum regeneration during selection after agroinfection, they used 0.1 M spermidine in the media after 3 weeks of callus development on selection. Addition of spermidine in the media resulted in three times more regeneration of transgenic plants (24% from 7%).

In their attempt to produce commercial GM wheat, Hu *et al.* (2003) at Monsanto carried out large-scale *Agrobacterium*-mediated transformation with an array of vectors carrying 5-enol-pyruvyl shikimate-3-phosphate synthase gene (governed by different promoters and transient peptides) from the *Agrobacterium* strain CP4. This CP4 confers resistance to glyphosate and serves as a selection marker besides being a gene of interest. More than 3000 transformation events were produced with an average transformation efficiency of 4.4%. The entire procedure was completed in 80 days and first Roundup Ready (glyphosate tolerant) commercial wheat was produced for field trail. However, the genotype used in the study was Bobwhite, which is of little agronomic importance. The comparison with biolistic transformation was also done simultaneously and it was found that *Agrobacterium*-mediated transformation resulted in more single copy transgenics (66%) and around half of them showed Mendelian inheritance of 3:1. Moreover, transgene expression was stable up to T_9 generation.

Toward developing transgenics of Polish winter wheat, Przetakiewicz *et al.* (2004) used three combinations of *Agrobacterium tumefaciens* strains and vectors. They used two hypervirulent strains, AGL1, containing the pDM805 binary plasmid, and EHA101, containing pGAH and the common *Agrobacterium* strain LBA4404, harboring the super binary pTOK233 vector. The pDM805 contained *bar* under the control of *Ubi1* promoter, pGAH had *nptII* under *nos*, and pTOK233 had *hpt* under CaMV 35S. Additionally, pDM805 and pTOK233 carried the *gus* reporter gene under the *Act1* promoter or 35S promoter, respectively. They obtained 12.6% transformation efficiency (highest reported) with EHA101 (pGAH) on a kanamycin-containing medium. The second best combination was LBA4404 (pTOK233) with kanamycin selection, which gave an average transformation rate of 2.3%. Phosphinothricin selection gave 1.0% transformation efficiency, while hygromycin, depending on the strain/vector used, gave from 0.2% to 0.4%. PCR analysis of T₁ revealed that 67% of the lines showed a 3:1 segregation ratio, and 11% a 15:1 ratio, while in 22%, segregation was non-Mendelian.

In a nonconventional approach through *Agrobacterium*-mediated genetic transformation in wheat, Sawahel and Hassan (2002) injected *Agrobacterium* inoculum directly into spikelets just before anthesis. The strain used in the study was LBA4404 and the vector was pBI-P5CS carrying *nptII* and *Vigna aconitifolia* Δ' -pyroline-5-carboxylate synthetase complementary DNA (cDNA), for proline biosynthesis. A transformation frequency of 0.9% was achieved and the transgenics were analyzed by Southern, Northern, and Western analysis of P5CS product. However, this method has not been exploited since by other workers.

Besides bread wheat (*Triticum aestivum* L.), *Agrobacterium*-mediated transformation was extended to tetraploid emmer wheat (*Triticum dicoccum* Schuble) by Khurana *et al.* (2002). Two commercial *dicoccum* wheat cultivars, namely DDK1001 and DDK1009, were transformed with LBA4404 with two different vector constructs (p35SGUSINT and pBI101:act1) using a variety of explants. Both the constructs had *nptII* as selection marker and *gus* as the reporter gene. Mature embryo-derived calli were found to be more effective than any other explant and

it was concluded that the monocot promoter *act1* is four times more effective in terms of transient GUS expression than CaMV 35S promoter. In a subsequent study, Chugh and Khurana (2003) made a comparison between particle bombardment and *Agrobacterium*-mediated transformation of bread and emmer wheat using basal segments as explants. LBA4404 carrying pCambia3301 and vector pAHC25 were used for *Agrobacterium*-mediated and direct gene transfer through particle bombardment. Both vectors had *bar* gene for selection and *uidA* as reporter gene. Transformation efficiency in the range of 4% was obtained with particle bombardment, whereas it was 7.5% using *Agrobacterium*. More recently, Patnaik *et al.* (2006) successfully transformed six different commercial Indian cultivars of bread and *durum* wheat with a variety of constructs and optimized several key factors such as explants, efficiency of selection gene, and performance of different promoters in effecting expression of transgene. In this study, direct transformation of mature embryo explants was done to minimize the loss of regeneration potential due to prolonged culture procedures, thus opening the possibility for mature embryo explants as they are not only easily available but large numbers can also be handled simultaneously.

2.1.3 Other approaches toward wheat transformation

For the first time, Sautter *et al.* (1991) constructed a novel microprojectile accelerating system for efficient gene transfer into cells *in situ* that avoids binding DNA to microprojectiles and keeps the DNA in solution. Instead of a macroprojectile (or the equivalent), the particles were accelerated in a Bernoulli air stream. This micro-targeting approach directed highly dispersed particles to sites with diameters as little as 0.15 mm, allowing precise aiming to restricted tissues. Transient expression of the *Escherichia coli* β -glucuronidase gene in immature wheat embryo scutella was obtained at a frequency of up to 3% of the treated cells in the surface layer. Zhu *et al.* (1993) reported transformation and regeneration of wheat protoplasts by plasmid pCGN1055 containing *hpt* gene under control of a plant promoter by cationic liposomes (lipofectin).

Transformation frequency of 6.0% and 8.8% was reported based upon hygromycin resistance and DNA molecular hybridization studies. However, the plants regenerated were albinos.

Exogenous DNA uptake and transient expression of the *gus* reporter gene was studied in wheat zygotic embryos employing a simple procedure of cellular permeabilization by Mahalakshmi *et al.* (2000). Use of membrane inactive agents like saponin and toluene resulted in uptake of expression vectors in mature as well as immature embryos. Variation of GUS activity was not different among the three genotypes tested in the study suggesting relative genotype independence of the method. Initially developed by Kaeppler *et al.* (1992), silicon carbide whisker-mediated stable transformation system was adopted by Brisibe *et al.* (2000) for different lines of wheat anther culture and compared with microprojectile bombardment technology. They used a variety of vectors with different selection markers and found that after 2 months of selection pressure, silicon carbide whisker-mediated transformed cell lines had 28–64% recovery while recovery for microprojectile bombarded cell lines was 15–36% only.

In an alternative approach for particle bombardment, electroporation was used effectively to deliver DNA into the tissue of intact but immature embryos by Sorokin *et al.* (2000). Transformed plantlets were recovered after electroporation using field strengths of 275 and 750 Vcm⁻¹, 960-μF capacitor, and 50 μgml⁻¹ of linear plasmid DNA, containing *bar* and *uidA* genes. A field strength of 750 Vcm⁻¹ proved to be more effective for DNA delivery (estimated by transient GUS expression) and for recovery of transformed plants (two transgenic plants were recovered with an efficiency of 0.4%). After application of field strength of 275 Vcm⁻¹ there was no visual evidence of transient GUS expression, but one transgenic plant was recovered with an efficiency of 0.2%, based on the number of electroporated embryos. Southern blot hybridization revealed a low copy number of transgene integration with some rearrangements at the integrated loci. None of the transgenic plants showed any visible GUS expression, however, RT-PCR analysis showed presence of *uidA* gene. This may indicate that suppression of *uidA* expression occurred at the post-transcriptional level, as also suggested by Bahieldin *et al.* (2005a). Use of electroporation to

effectively deliver DNA into the tissue of intact wheat immature embryos was also reported by Liang *et al.* (2005). Several physical parameters were optimized such as field strength, capacitor strength, and amount of plasmid. Electroporation was carried out by a portable and permanent ring electrode that can be fitted into the wells of 24-well plates and samples pulsed three times. Integration of the introduced genes into the genome of transgenic plants was shown by PCR and Southern analysis. Transformation frequency was 7.5% much higher than 4.2% by microprojectile bombardment.

A modified, nondamaging protocol for the production of fertile transgenic wheat (*T. aestivum* L. cv. Giza 164) plants by laser micropuncture was reported by Badr *et al.* (2005). The new indigenous setup secured transformation of as many as 60 immature embryo-derived calli (10 000 cells each) in less than 1 h using a UV excimer laser with two-dimensional translation stages, a suitable computer program and a proper optical system. Five-day-old calli were irradiated by a focused laser microbeam to puncture momentarily made self-healing holes (approximately 0.5 μm) in the cell wall and membrane to allow uptake of the exogenous DNA. The plant expression vector pAB6 containing *bar* gene as a selectable marker and GUS (*uidA*) gene as a reporter gene were used for transformation. Induced calli without any selection pressure were transferred to a modified MS medium with 1 mg l⁻¹ Bialaphos for regeneration followed by more stringent selection on 2 mg l⁻¹ Bialaphos for rooting. Three regenerated transgenic events were evaluated for the integration and stable expression of both genes.

2.2 Wheat Transgenics for Functional Genomics Analysis

Takumi *et al.* (1999) for the first time used wheat as a system to investigate the excision of a maize transposable element in wheat cells. The *uidA* gene expression indicated that the *Ds* excision was observed only in the transgenic callus lines stably expressing the *Ac* transposase gene. Drakakaki *et al.* (2000) employing particle bombardment produced transgenic wheat and rice plants expressing recombinant soybean ferritin, a protein that can store large amounts of iron,

expressed using the constitutive maize *ubiquitin-1* promoter, and showed that iron levels increased in vegetative tissues by 50% in R₂ generation of transgenic plants.

Stoger *et al.* (2001) used heterologous cereal system of wheat endosperm to produce, isolate, and crystallize 11S legume globulins for structural analysis and characterization of other important seed storage proteins of legumes. To study a single type of homogenous legumin they produced pea legumin A in transgenic wheat (*T. aestivum*) endosperm where prolamins are predominant, confirming that high-level production of a single type of legumin polypeptide also results in spontaneous crystal formation of *in vivo*. Kluth *et al.* (2002) undertook a detailed analysis of granule bound starch synthase 1 (GBSS1) promoter with the chimeric constructs of 5' deletions of *gbss1* gene with β -glucuronidase gene. They found that promoter activity was decreased with deletions below -4 kb. Beecher *et al.* (2002) showed that the pinB-D1b alteration, common in hard textured wheat, can be complemented by the expression of wild-type pinB-D1a in transformed plants. These results indicate that the pinB-D1b alteration is most likely the causative Ha mutation in the majority of hard wheat.

Laurie *et al.* (2002) successfully transformed wheat with both sense and antisense constructs of high affinity potassium transporter HKT1 and characterized it with different magnitudes of salt stress suggesting its role in the roots of wheat plants and the Na⁺:K⁺ ratios were reduced in salt stressed transgenic tissue when compared with controls. Rasco-Gaunt *et al.* (2003) characterized the constitutive maize Histone H2B promoter in both wheat and maize tissues using the *gusA* reporter gene and two synthetic versions of the *pat* (phosphinothricin acetyl transferase) selectable marker gene, namely mopat and popat. Analyses of transgenic plants showed that the H2B promoter is able to drive the expression of *gusA* to strong, constitutive levels in wheat and maize tissues. However, expression in the tissues was particularly strong in the floral tissues, in the young parts of the leaf and root tissues and in the meristems.

Huang *et al.* (2003) reported map-based cloning of the leaf rust resistance gene *Lr21*, previously mapped to a gene-rich region at the distal end of chromosome arm 1DS of bread wheat (*T. aestivum*

L.). Cloning of *Lr21* was confirmed by genetic transformation and by a stably inherited resistance phenotype in transgenic plants of susceptible genotype "Fielder." Yong *et al.* (2003) isolated a vernalization-related gene *VER2* from winter wheat (*T. aestivum* L.) using a differential screening approach and characterized it through transgenic approach involving antisense technology. Antisense inhibition of *VER2* in transgenic wheat showed that heading and maturation time were delayed up to 6 weeks. Tissue degeneration at the top of the spike was also noticed in the antisense-inhibited transgenic wheat suggesting that *VER2* plays an important role in vernalization signaling and spike development in winter wheat. In another interesting report, Yan *et al.* (2004) explored molecular difference between winter and spring wheat. They reported positional cloning of wheat vernalization gene *VRN2*, a dominant repressor of flowering that is down-regulated by vernalization. Through RNA interference (RNAi) they obtained transgenic winter wheat plants that have reduced flowering time of at least 1 month less than control wild type. Later, Loukoianov *et al.* (2005) characterized another vernalization gene of wheat *VRN1* and showed its interaction with *VRN2*, involving transgenic approach. They showed that the level of *VRN1* transcripts in early developmental stages is critical for flowering initiation. A reduction of *VRN1* transcript levels by RNAi delayed apex transition to the reproductive stage, increasing the number of leaves, and delayed heading time by 2–3 weeks.

Zuther *et al.* (2004) through transgenic approach in wheat made a detailed analysis of acetyl-CoA carboxylase (ACC) gene and confirmed presence of nested promoter governing differential response in cell organelles. The internal promoter is located in an intron removed from transcripts originating at the first promoter. These complex promoters, which are different for the cytosolic and plastid *ACC* gene control tissue-specific expression of the enzymatic activity supplying cytosolic, plastid, and mitochondrial pools of Melonyl-Co A. Wang *et al.* (2005) cloned and characterized a Ca²⁺ permeable channel gene *TaTPC1* of wheat. *TaTPC1* transgenic plants exhibited more stomatal closing in the presence of Ca²⁺ than the control, supporting a role for the calcium channel in regulating plant responses to environmental change.

Global comparative gene expression analysis is potentially a very powerful tool in the safety assessment of transgenic plants, since it allows for the detection of differences in gene expression patterns between a transgenic line and the mother variety. Gregersen *et al.* (2005) undertook global gene expression analysis of developing seeds of transgenic and nontransgenic wheat plants. Comparisons and statistical analyses of the gene expression profiles, however, revealed only slight differences at the three developmental stages. First complementation study through transgenic technology in wheat was done by Martin *et al.* (2006) when they restored wild-type (soft) phenotype in a *Pin a* null mutant having hard phenotype, additionally suggesting that both *Pin a* and *Pin b* genes need to be present for friabilin formation and soft grain.

The *Q* gene in wheat pleiotropically influences many other domestication-related traits such as glume shape and tenacity, rachis fragility, spike length, plant height, and spike emergence time. Simons *et al.* (2006) isolated the *Q* gene and verified its identity by analysis of knock-out mutants and transformation. The *Q* allele is more abundantly transcribed than *q*, and differs in a single amino acid. Rachis fragility, glume shape, and glume tenacity mimicked the *q* phenotype in transgenic plants exhibiting post-transcriptional silencing of the transgene and the endogenous *Q* gene. Variation in spike compactness and plant height was associated with the level of transgene transcription suggesting dosage effects of *Q*.

2.3 Wheat Transgenics for Biotic Stress Tolerance

2.3.1 Fungal resistance

Clausen *et al.* (2000) cloned a cDNA encoding the antifungal protein KP4 (killing protein) from double-stranded RNA virus, infecting *Ustilago maydis* and this cDNA was inserted behind the ubiquitin promoter of maize and genetically transferred to wheat varieties particularly susceptible to stinking smut (*T. tritici*) disease. The transgene was integrated and inherited over several generations. Of seven transgenic lines, three showed antifungal activity against *U. maydis*. The antifungal activity

correlated with the presence of the *KP4* transgene. *KP4*-transgenic, soil-grown wheat plants exhibit increased endogenous resistance against stinking smut. Similarly Oldach *et al.* (2001) introduced three cDNAs encoding the antifungal protein Ag-AFP from the fungus *Aspergillus giganteus*, a barley class II chitinase and a barley type I RIP, all regulated by the constitutive *Ubiquitin1* promoter from maize, in transgenic wheat. Heterologous expression of the fungal *afp* gene and the barley *chitinase* II gene in wheat demonstrated that colony formation and, thereby, spreading of two important biotrophic fungal diseases was inhibited approximately 40–50% at an inoculum density of 80–100 spores/cm².

Altpeter *et al.* (2005) developed a novel epidermis-specific promoter to enhance resistance of wheat to the powdery mildew fungus *Blumeria graminis* f. sp. *tritici*, with two defense-related genes. A 2.3 kb fragment of the wheat epidermis-specific *GstA1* promoter was used for overexpression of oxalate oxidase 9f-2.8 and *TaPERO* peroxidase, two defense-related wheat genes expressed in inner leaf tissues. Transient as well as stable overexpression of the *TaPERO* peroxidase gene in wheat epidermis under the control of the *GstA1* promoter resulted in enhanced resistance against *B. graminis* f. sp. *tritici*, whereas oxalate-oxidase overexpression had no effect in either system. To increase resistance against fungal pathogens through phytoalexins, two resveratrol synthase genes *vst1* and *vst2* from grapevine (*Vitis vinifera* L.) and the pinosylvin synthase gene *pss* from pine (*Pinus sylvestris* L.) under stress-inducible grapevine promoters were stably transformed into bread wheat by Serazetdinova *et al.* (2005). The *vst1* and *vst2* promoters were functional in wheat. Upon inoculation with the biotrophic pathogen *Puccinia recondita* f. sp. *tritici* several *vst* expressing wheat lines showed a significant reduction of disease symptoms ($19 \pm 9\%$ to $27 \pm 8\%$) compared to wild-type plants.

Mackintosh *et al.* (2006) evaluated the feasibility of using the rapid-maturing dwarf wheat cultivar Apogee as an alternative genotype for transgenic *Fusarium* head blight (FHB) resistance research. With comparable transformation efficiency (1.33%), Apogee was also found to exhibit high FHB susceptibility and reached anthesis within 4 weeks. A microsatellite marker haplotype analysis

of the chromosome 3BS FHB resistant QTL) region indicated that this region may be deleted in Apogee, indicating that Apogee is particularly well suited for accelerating transgenic FHB resistance research and transgenic wheat research in general.

Genes encoding pathogenesis-related (PR) proteins (chitinase and β -1,3-glucanase) were transformed into spring wheat, “Bobwhite” using a biolistic transformation protocol, with the goal of enhancing levels of resistance against scab (Anand *et al.*, 2003a). Twenty-four putative transgenic lines expressing either a single PR-protein gene or combinations thereof were regenerated. Transgene expression in a majority of these lines (20) was completely silenced in the T₁ or T₂ generations. Transgenic plants when bioassayed against scab showed a delay in the spread of the infection (type II resistance) under greenhouse conditions. However, none of the transgenic lines had resistance to scab in the field under conditions of strong pathogen, suggesting these plants lacked effective resistance to initial infection (type I resistance) under these conditions (Anand *et al.*, 2003b).

To enhance fungal disease resistance, wheat plants (cv. Bobwhite) were engineered to constitutively express the potent antimicrobial protein Ace-AMP1 (a lipid transfer protein from *A. cepa*), driven by a maize *ubiquitin* promoter along with its first intron by Roy-Barman *et al.* (2006). The levels of Ace-AMP1 in different transgenic lines correlated with the transcript levels of the transgene. Up to 50% increase in resistance to *B. graminis* f. sp. *tritici* was detected in detached leaf assays. In ears of transgenic wheat inoculated with *Neovossia indica*, *Ace-AMP1* intensified expression of defense-related genes and elevated levels of salicylic acid and of transcripts of phenylalanine ammonia lyase (PAL), glucanase (PR2), and chitinase (PR3) in the transgenic plants indicated manifestation of systemic acquired resistance (SAR). Makandar *et al.* (2006) showed that the *Arabidopsis thaliana* *NPR1* gene (*AtNPR1*), which regulates the activation of SAR, when expressed in the FHB-susceptible wheat cv. Bobwhite, confers a heritable, type II resistance to FHB caused by *Fusarium graminearum*. The enhanced FHB resistance in the transgenic *AtNPR1*-expressing wheat is associated

with the faster activation of defense response when challenged by the fungus, suggesting that *NPR1* is an effective candidate for controlling FHB.

Zhao *et al.* (2006) addressed two common issues of wheat biotechnology, to improve the transformation efficiency of wheat (*T. aestivum* L.) mediated by *Agrobacterium tumefaciens* and to make transgenics with higher level of fungal resistance. They explored the possibility of employing the basal portion of wheat seedling (shoot apical meristem) as the explants in three genotypes of wheat and transformed by *A. tumefaciens* carrying β -1, 3-glucanase gene. A total of 27 T₀ transgenic plants were obtained, and the average transformation efficiency was as high as 9.82%. Investigation of the T₂ plants revealed that some transformed plants had higher resistance to powdery mildew than the controls.

2.3.2 Viral resistance

Wheat (*T. aestivum* L. cv. Hi-Line) immature embryos were transformed with the replicase gene (*NIb*) of wheat streak mosaic virus (WSMV) by Sivamani *et al.* (2000b) through biolistic method. Transgenic plants showed various degree of resistance to WSMV. Two lines displayed higher resistance with very mild virus symptoms after inoculation and the new growth of 72% and 32% plants from these lines, respectively, were asymptomatic and had no detectable virus throughout the plant life cycle. In a later study, the same group stably transformed wheat plants with the coat protein (CP) gene of WSMV (Sivamani *et al.*, 2002). One transgenic line showed high resistance to inoculations of two WSMV strains. This line had milder symptoms and lower virus titer than control plants after inoculation. Northern hybridization indicated a high level of degraded CP-mRNA expression. However, when field evaluation was done for the plants from above the two experiments by Sharp *et al.* (2002), none of the transgenics performed better than the wild types under both virus-challenged and control conditions.

To produce virus resistant transgenic wheat plants, an *rnc70* gene encoding a mutant bacterial ribonuclease III (RNase III) was introduced by Zhang *et al.* (2001) through microprojectile

bombardment. T₁, T₂, and T₃ plants regenerated from three callus lines were challenged with barley stripe mosaic virus, and plants expressing RNase III exhibited a high level of resistance to the virus infection as evidenced by the absence of virus symptoms and reduced accumulation of virions in these plants.

2.3.3 Nematode resistance

Serine proteinase inhibitors (PIs) are proteins found naturally in a wide range of plants with a significant role in the natural defense system of plants against herbivores. Vishnudasana *et al.* (2005) engineered a plant serine PI (*pin2*) gene into *T. durum* cv. PDW215 by *Agrobacterium*-mediated transformation to combat cereal cyst nematode (*Heterodera avenae*) infestation with a transformation efficiency of 3% using mature embryo as explant. The *PIN2* systemic expression confers satisfactory nematode resistance. The correlation analysis suggests that at $p < 0.05$ level of significance the relative PI values show a direct positive correlation *vis-à-vis* plant height, plant seed weight, and also the seed number.

2.4 Wheat Transgenics for Abiotic Stress Tolerance

To obtain resistance against abiotic stress, Sivamani *et al.* (2000a) introduced the ABA-responsive barley gene *HVA1*, a member of group 3 late embryogenesis abundant (LEA) protein genes, into spring wheat (*T. aestivum* L.) cv. Hi-Line using the biolistic bombardment method. High levels of expression of the *HVA1* gene, regulated by the maize *ubi1* promoter, were observed in leaves and roots of independent transgenic wheat plants and inherited to offspring generations. When tested in control environmental conditions, the transgenic plants had higher water use efficiency values, significantly greater total dry mass, root fresh and dry weights, and shoot dry weight compared to the controls under soil water deficit conditions. Four selected transgenic lines were tested in nine field experiments over six cropping seasons and one promising line was selected for commercialization (Bahieldin *et al.*, 2005b).

Biosynthesis of mannitol improves tolerance to water stress and salinity. Abebe *et al.* (2003) showed ectopic expression of the *mtlD* gene in wheat (*T. aestivum* L. cv. Bobwhite) and tolerance to water stress and salinity was evaluated using calli and T₂ plants transformed with or without *mtlD*. However, the amount of mannitol accumulated in the callus and mature leaf was not in accordance with the performance of transgenics over wild type, concluding that the improved growth performance of mannitol-accumulating calli and mature leaves was probably due to other stress-protective functions of mannitol, although possibility of osmotic effects in growing regions of the plant cannot be ruled out.

Khanna and Daggard (2006) produced transgenic wheat lines through microprojectile bombardment of immature embryos of spring wheat cultivar Seri 82 with a recombinant antifreeze gene, *rAFPI*, targeted to the apoplast using a Murine leader peptide sequence from the mAb24 light chain for retention in the endoplasmic reticulum using a C-terminus KDEL sequence. Transgenic wheat line T-8 with apoplast-targeted antifreeze protein exhibited the highest levels of antifreeze activity and provided significant freezing protection even at temperatures as low as -7°C .

2.5 Wheat Transformation for End Product Use

Although several cases of successful and stable wheat transformation were reported till 1996, Bleschl and Anderson (1996) for the first time transformed wheat to change the amount and composition of high-molecular-weight glutenin subunits (HMW-GS), a class of seed storage proteins via genetic engineering. A gene encoding a novel hybrid subunit under the control of native *HMW-GS* regulatory sequences was inserted into wheat. Of 26 independent transgenic lines identified by Bialaphos selection, 18 expressed the co-transformed hybrid *HMW-GS* gene in their seed. The hybrid subunit accumulated to levels comparable to those of the native *HMW-GS*. Transgene expression was stable for at least three seed generations in the majority of lines and results showed that a native *HMW-GS* gene promoter can be used to obtain high levels of expression

of seed storage and, potentially, other proteins in wheat endosperm. Shimoni *et al.* (1997) studied the structural requirements for the assembly of HMW-GS, a recombinant protein between two cognate x- and y-type subunits expressed in transgenic wheat. In contrast to the naturally polymerized x- and y-type HMW-GS, a significant amount of the recombinant subunit remained monomeric, showing the possibility of modifying gluten assembly by expressing recombinant HMW-GS in transgenic wheat, thus having major implications for the improvement of wheat bread-making quality adjustment for end product need.

Altpeeter *et al.* (1996) transformed wheat with another gene of interest when they introduced the HMW-GS *1Ax1* gene, known to be associated with good bread-making quality into the Bobwhite cultivar of wheat (*T. aestivum* L.), in which it is not present naturally. Of the 21 independent transformed lines selected, 20 expressed the selectable *bar* gene, and nine the *1Ax1* gene. The amount of HMW-GS *1Ax1* protein produced in the different transgenic lines varied from 0.6% to 2.3% of the total protein, resulting in an increase of up to 71% in total HMW-GS proteins. The transgenic plants were normal, fertile, and showed Mendelian segregation of the transgenes. It has been found that the accumulation of HMW-GS *1Ax1* was consistent and stable up to the R₃ seed generation. Popineau *et al.* (2001) studied the effect of transgenes coding for subunits *1Ax1* and *1Dx5* in two near-isogenic wheat lines differing in their HMW subunit compositions and mixing properties. Overexpression of *1Ax1* and *1Dx5* subunits modified glutenin aggregation, but glutenin properties were much more affected by expression of the *1Dx5* transgene. This resulted in increased cross-linking of glutenin polymers. In dynamic assay, the storage and loss moduli of hydrated glutes containing *1Dx5* transgene subunits were considerably enhanced, whereas expression of the *1Ax1* transgene had a limited effect.

Agronomic traits and yield components were studied in seven transgenic lines of wheat in which four lines contained the transgenes for β -glucuronidase (*uidA*), herbicide resistance (*bar*), and for one HMW subunit, and three lines contained a transgene for one HMW glutenin subunit with no marker genes, and compared with the nontransgenic parent and null segregant

lines under field conditions during two agronomic years (Barro *et al.*, 2002). All transgenic lines had a longer heading date than the parents and no other differences were found between the lines constitutively expressing the *uidA* and *bar* genes from those which expressed only the HMW genes. Among the traits studied such as number of flowers per spike, flower fertility, harvest index, test weight, and grain protein content differences between transgenic lines and the parents were small, and could be eliminated by backcrossing transgenic lines with their parents and selecting for the wanted genotypes.

Yield in cereals is a function of seed number and weight; both parameters are largely controlled by seed sink strength. The allosteric enzyme ADP-glucose pyrophosphorylase (AGP) plays a key role in regulating starch biosynthesis in cereal seeds and is most likely the important determinant of seed sink strength. Toward overcoming the yield barrier during stress environments, Smidansky *et al.* (2002) transformed wheat with a modified form of the maize (*Zea mays* L.) *Shrunken2* gene (*Sh2r6hs*), which encodes an altered AGP large subunit. The *Sh2r6hs* transgene was functional after five generations in wheat. Developing seeds from *Sh2r6hs* transgenic wheat exhibited increased AGP activity in the presence of a range of orthophosphate concentrations *in vitro*. Transgenic *Sh2r6hs* wheat lines produced on average 38% more seed weight per plant. Total plant biomass was increased by 31% in *Sh2r6hs* plants.

Although the wheat grain is an excellent source of energy in the form of metabolizable carbohydrates and also provides protein, it has an important nutritional shortcoming with respect to phosphate, as phosphate is stored in the form of phytic acid, which is largely indigestible to humans and other monogastric animals. For a plausible solution wheat transformation was done by Brinch-pedersen *et al.* (2000) with an *Aspergillus niger* phytase encoding gene (*phyA*) under maize *ubiquitin1* promoter and wheat α -amylase signal peptide (Ubi-SP-Phy) for endosperm localization. The Ubi-SP-Phy transgenic seeds showed up to fourfold increase of phytase activity. Later on, transgenic wheat materials possessing wheat endogenous 6-phytase and *Aspergillus* 3-phytase activities under the control of the maize *ubiquitin1* promoter and the wheat HMW-GS

IDX5 promoter, respectively were comparatively analyzed (Brinch-Pedersen *et al.*, 2003) and it was found that heterologous phytase synthesized in the endosperm efficiently hydrolyzed inositol phosphates in flour of transgenic seeds. To explore the role of subunits of low-molecular weight (LMW)-glutenins on quality parameters of complex gluten system in starchy endosperm of wheat, Tosi *et al.* (2004) transformed pasta (*T. durum*) wheat cultivars. In this work, a range of transgene expressions was observed, and analysis carried out in independent transgenic lines showed that the transgenic protein was incorporated in the glutenin polymers.

Recently, Shewry *et al.* (2006) analyzed a series of transgenic wheat lines expressing additional HMW subunit genes produced by Barro *et al.* (1997) and the corresponding control lines in replicated field trials at two sites in UK over 3 years with successive generations of the transgenic lines being planted. Detailed statistical analyses showed that the transgenic and nontransgenic lines did not differ in terms of stability of HMW subunit gene expression or in stability of grain nitrogen, dry weight, or dough strength, either between the 3 years or between sites and plots indicating that the transgenic and control lines can be regarded as substantially equivalent in terms of stability of gene expression between generations and environments.

3. FUTURE OUTLOOK

The obvious merits of *Agrobacterium*-mediated wheat transformations are becoming more apparent and emerge as the method of choice due to its ease of use, low costs, and the unique ability to introduce single or low copy numbers of the intact transgene. Presently, attempts have been made to develop transgenic wheat without the aid of either a selection pressure or a selectable marker. Successful transformation in wheat still remains a multidisciplinary approach that is mainly dependent on efficient and reliable tissue culture techniques for regeneration of viable transgenic plants. The advances in molecular markers and mapping technologies along with the recent techniques to construct large DNA insert libraries can speed up the discovery and character-

ization of genes for complex traits. The genetic transformation combined with the advances in genomics, proteomics, and bioinformatics opens up tremendous possibilities to genetically engineer ideotype with desirable complex traits to satisfy producers and consumers of wheat.

1. INTRODUCTION

1.1 Barley Taxonomy and Systematics

Barley, generic name *Hordeum*, is classified within the tribe Triticeae of the family Gramineae. The tribe Triticeae also encompasses some of the other economically important crops such as wheat, rye, and triticale. Barley has been regarded as the third founder cereal of Old World Neolithic agriculture; the first two being einkorn wheat (*Triticum monococcum*) and emmer wheat (*Triticum dicoccoides*) (Harlan and Zohary, 1966; Zohary, 1973; Zohary and Hopf, 2000). It is believed that domesticated barley had its beginnings about 10 000 years ago in the Fertile Crescent (Zohary and Hopf, 2000). Two-row types with brittle rachis, bearing similarity to *Hordeum spontaneum*, were considered to be the progenitors for the domestication of barley (Zohary and Hopf, 1988). *H. spontaneum* as such is thought to be the wild ancestor of present day cultivated barley, *Hordeum vulgare* L. (Harlan and Zohary, 1966; Zohary, 1969).

The genus *Hordeum*, although considered simpler than the other temperate cereals, has been disputed as to its species level delineation and it has been suggested that it be subdivided into sections based on genomic variation, with the recognition

of 32 species, totaling 45 taxa (Bothmer *et al.*, 1995; Table 1). Across these 45 taxa, the basic chromosome number of $x = 7$ is represented as diploid ($2n = 2x = 14$), tetraploid ($2n = 4x = 28$), and hexaploid ($2n = 6x = 42$) (Table 1).

Besides cytotype delimitation, systematics of the genus *Hordeum* has included studies based on morphology, distribution, cytogenetics, isozymes, and DNA markers. It would be prudent to state that a combination of all these approaches is likely to lead to a more comprehensive understanding of the genus *Hordeum*. However, aside from the semantics of *Hordeum* systematics, the subsequent purpose for an understanding of systematics is to allow use of exotic germplasm for improvement of cultivated barley through wide hybridization (see Section 1.4.3). Morphologically, the *Hordeum* species are characterized by three one-flowered spikelets positioned at the rachis node, with all three spikelets being fertile in six-row barleys and the central spikelet being fertile in two-rowed barleys (Bothmer and Jacobsen, 1985; Bothmer *et al.*, 1995). The most determinant delimiting morphological traits for distinguishing the various *Hordeum* species are based on the entire spike as well as on the spikelets, although an assessment of different criteria has been suggested to more likely give proper characterization of the species (Bothmer and Jacobsen, 1985).

Table 1 Subdivision of the genus *Hordeum* into sections and species delineation^(a)

Section	Species	Ploidy status	Origin
Hordeum	<i>H. bulbosum</i> L.	2x, 4x	Mediterranean region, eastward to Afghanistan, and south Tadjikistan
	<i>H. murinum</i> ssp. <i>glaucum</i> (Steudel) Tzvelev	2x	Southern Mediterranean, eastward to Iran, Afghanistan, and Kashmir
	<i>H. murinum</i> ssp. <i>leporinum</i> (Link) Arcangeli	4x, 6x	Mediterranean region, eastward to Afghanistan, Turkey, and eastward to Iran
	<i>H. murinum</i> ssp. <i>murinum</i> L.	2x, 4x, 6x	Northern and western Europe
	<i>H. vulgare</i> ssp. <i>vulgare</i>	2x	Mediterranean region, Ethiopia, south-west Asia eastward to China and Japan, now cultivated in all temperate agricultural zones
	<i>H. vulgare</i> ssp. <i>spontaneum</i>	2x	Greece, Egypt, south-west Asia eastward through Iran, Afghanistan, western Pakistan, and southern Tadjikistan
Anisolepis	<i>H. chilense</i> Roemer and Schultes	2x	Central Chile and western-most parts of Neuquen and Rio Negro provinces of Argentina
	<i>H. cordobense</i> Bothmer, Jacobsen, and Nicora	2x	Central and northern Argentina
	<i>H. euclaston</i> Steudel	2x	Central Argentina, Uruguay, and southern Brazil
	<i>H. flexuosum</i>	2x	Province of Buenos Aires, Argentina and dispersed around adjacent areas including Uruguay
	<i>H. intercedens</i> Nevski	2x	Endemic to southwestern California, adjacent Santa Barbara Islands and north-west Baja California of Mexico
	<i>H. muticum</i> Presl	2x	Northwestern Argentina, northeastern Chile, Bolivia, Peru, Ecuador, and Colombia
	<i>H. pusillum</i> Nuttall	2x	Most of United States except western-most region, few records from Canada and Mexico
	<i>H. stenostachys</i> Gordon	2x	Central and northern Argentina, Uruguay, and southern-most Brazil
Critiesion	<i>H. arizonicum</i> Covas	6x	Primarily in southern Arizona, few locations in south-east California and northern Mexico
	<i>H. comosum</i> Presl	2x	Restricted to Andean areas in Chile and north Argentina to the province of Mendoza
	<i>H. halophilum</i> Grisebach	2x	From Tierra del Fuego northward on both sides of the Andes through Argentina and Chile, dispersed in Bolivia and Peru
	<i>H. jubatum</i> L.	4x	Native from Mexico, northward through the United States, Canada, and Alaska to eastern Siberia
	<i>H. lechleri</i> (Steudel) Schenck	4x	Restricted to Chile and Argentina from the province of Mendoza and southward to Tierra del Fuego; also on Falkland Islands
	<i>H. procerum</i> Nevski	4x	Mainly in the provinces of Buenos Aires, Rio Negro, and La Pampa of Central Argentina; single record from Uruguay
	<i>H. pubiflorum</i> Hooker F.	2x	Mainly in Tierra del Fuego and the Magellanes, the province Santa Cruz in Argentina, single record from Nuble in Chile
Stenostachys	<i>H. bogdanii</i> Wilensky	2x	Central Asia, western Iran, Afghansitan, north and west Pakistan, north India, south Siberia, Mongolia, and north China
	<i>H. brachyantherum</i> ssp. <i>brachyantherum</i> Nevski	4x, 6x	Western North America, from Baja California in Mexico northward to Alaska and the Aleutian islands
	<i>H. brachyantherum</i> ssp. <i>californicum</i> (Covas and Stebbins) Bothmer, Jacobsen, and Seberg	2x	Endemic to southwestern California up to north of Bay area

<i>H. brevisubulatum</i> ssp. <i>brevisubulatum</i> (Trinius) Link	2x, 4x	South-eastern Siberia, Mongolia, and northern China
<i>H. brevisubulatum</i> ssp. <i>iranicum</i> Bothmer	4x, 6x	Western and southern Iran in the Zagros and the Alborz Mountains
<i>H. brevisubulatum</i> ssp. <i>nevskianum</i> (Nevski) Tzvelev	2x, 4x	Nepal, northern Kashmir in India, Chitral in Pakistan, western-most China, western Siberia, and north-eastern Afghanistan
<i>H. brevisubulatum</i> ssp. <i>turkestanicum</i> (Nevski) Tzvelev	4x, 6x	In restricted areas of central and north-eastern Afghanistan, Chitral (Pakistan), south Tadjikistan, and western-most China
<i>H. brevisubulatum</i> ssp. <i>violaceum</i> (Boissier and Hohenacker) Tzvelev	2x, 4x	Central Turkey, Caucasus, northern parts of east and west Azarbaijan in Iran, Alborz Mountains
<i>H. capense</i> Thunberg	4x	Republic of South Africa and Lesotho
<i>H. depressum</i> (Scribner and Smith) Rydberg	4x	Western United States
<i>H. erectifolium</i> Bothmer, Jacobsen, and Jørgensen	2x	Known only a single location in western part of Buenos Aires province of Argentina
<i>H. fuegianum</i> Bothmer, Jacobsen, and Jørgensen	4x	Tierra del Fuego and a few areas in Magellanes region of southern Chile
<i>H. guatemalense</i> Bothmer, Jacobsen, and Jørgensen	4x	Mountain region of Cuchumatanes in northern Guatemala
<i>H. marinum</i> ssp. <i>gussoneanum</i> (syn. <i>geniculatum</i>) (Parlatore) Thellung	2x, 4x	Eastern Mediterranean to south-west Asia (diploid); Turkey to Afghanistan (tetraploid)
<i>H. marinum</i> ssp. <i>marinum</i> Hudson	2x, 4x	Native in Mediterranean region
<i>H. parodii</i> Covas	6x	From northern part of Mendoza southward to Santa Cruz provinces of Argentina. Few dispersed locations in the province of Buenos Aires, in the region of Magellanes in south Chile, and Chilean side of Tierra del Fuego
<i>H. patagonicum</i> ssp. <i>magellanicum</i> (Parodi and Nicora) Bothmer, Giles, and Jacobsen	2x	From southern-most Patagonia with several localities inland to Tierra del Fuego
<i>H. patagonicum</i> ssp. <i>mustersii</i> (Nicora) Bothmer, Giles, and Jacobsen	2x	From two locations in Santa Cruz province
<i>H. patagonicum</i> ssp. <i>patagonicum</i> (Haumann) Covas	2x	Southern-most part of Chubut province and along the coast of Santa Cruz province
<i>H. patagonicum</i> ssp. <i>santacrucense</i> (Parodi and Nicora) Bothmer, Giles, and Jacobsen	2x	Southern part of Santa Cruz province, southward to Strait of Magellan
<i>H. patagonicum</i> ssp. <i>setifolium</i> (Parodi and Nicora) Bothmer, Giles, and Jacobsen	2x	Western part of Chubut province to north-west part of Santa Cruz province
<i>H. roshevitzii</i> Bowden	2x	Southern Siberia, Mongolia, and north-central China
<i>H. secalinum</i> Schreber	4x	From southern-most Sweden and central Denmark along Atlantic coast of Europe to Spain; scattered areas in Mediterranean and inland Europe; few locations in North Africa
<i>H. tetraploidum</i> Covas	4x	From province of Mendoza to province of Santa Cruz in Argentina

^(a)Reproduced from Bothmer *et al.* (1995)

Other distinguishing features have been based on geographic distribution, ecological niche, and reproductive habits (Bothmer and Jacobsen, 1985). Characterization at the genome level, including cytological studies is also valuable in evaluating *Hordeum* species relationships. Based on genome identity and meiotic pairing, Bothmer *et al.* (1983) were able to establish geographic distinctions among some of the diploid *Hordeum* species.

1.2 Barley Botany

The vegetative and reproductive attributes of the barley plant have changed considerably over the course of its evolution/domestication as has been the case for all the agriculturally important crops. Improvement, be it conscious or unconscious, has led to morphological changes suited to the needs and environments. There has been a range of

varietal distinctions based on the level of selection pressure applied, especially due to accelerated breeding efforts over the last 50 years to develop high performance crops with respect to yield as well as biotic and abiotic adversities. Thus, a generalized description of the barley plant would be adequate to address its botanical features in this section.

From a botanical perspective, growth and development of the barley plant from seed to maturity marks the fulfillment of its life cycle, as with all flowering plants. However, on a producer perspective, the grain must fulfill two important requirements, namely, efficient germination to ensure maximum crop stand and high grain yield to ensure profitability. Thus, knowledge of the components of the barley grain prior to the onset of the germination process *per se* would iterate the importance of some of its underlying features. A generalized mature barley grain consists of the husk (palea and lemma), pericarp (mature ovary wall), testa (seed coat), aleurone layer, starchy endosperm, and embryo (Figure 1). A distinguishing feature of commercial varieties of barley is the adherence and nonadherence of the husks to the grain, giving rise to hulled barley varieties and hullless or naked barley, respectively. Hullless barley is desirable as feed, while hulled barley is desirable for malting. The

Figure 1 Diagrammatic representation of a longitudinal section through a barley grain

barley grain without the husk is referred to as the caryopsis—a fruit with fused testa and pericarp. These two layers enclose the barley endosperm, which consists of the aleurone layer and the major starchy endosperm tissue. The aleurone layer is generally 2–4 cells thick. The basal part of the grain bears the embryo and consists of the root and shoot primordia, apical meristems, coleoptile, and scutellum.

The onset of germination of the barley grain is marked by the appearance of the coleorhiza (which encloses the primary and secondary roots) upon water imbibition. The importance of the germination process in barley is not only relevant from a crop stand establishment in the field, but also in the malting process wherein a uniform germination is desired for optimal malt production. Most of the physiological, biochemical, and molecular events during germination have been elucidated and documented (Briggs, 1978, 1992) and culminate into the emergence of the primary leaf above the soil surface, after breaking through the coleoptilar tip. The growth and development of the seedling proceed with further elongation of the “stem”, production of leaves, and emergence of tillers. The latter are generally predetermined axillary shoots. The number of tillers produced, although genetically determined, is influenced by growth conditions and often growth and development of the tillers are not fully realized under field conditions. Mature embryos induced to produce multiple shoots under *in vitro* culture conditions have been shown to be a result of prolific induction of axillary meristems in wheat and barley (Ganeshan *et al.*, 2003, 2006).

The transition from the vegetative to reproductive phase marks another important stage in the development of the barley plant. The spikelet primordia are generally initiated from the vegetative shoot apical meristem after the production of a certain number of leaves. This reproductive transition is marked by the double-ridge formation, wherein the apical meristem morphs from a single ridge (which represents the leaf primordia) to double ridge (which represents the spikelet primordia) (Briggs, 1978). Thereafter the development of the spike proceeds, enclosed within the flag leaf sheath during the course of its development. The spike subsequently emerges out of the sheath and anthesis generally occurs while the spike is still within the sheath (boot).

1.3 Cultivation and Economic Importance

Since the dawn of agriculture, barley has steadily gained value and its importance, in terms of economic and consumer attributes, is constantly being re-evaluated. Novel uses for nutraceutical, pharmaceutical, and industrial applications are being explored to diversify its cultivation. But to date barley has primarily been of great economic importance for the malting and brewing industry and as animal feed. Barley has worldwide growing regions extending from temperate climatic zones to high altitudes. Versatile climatic regimens often provide necessary impetus for cultivation of barley. The estimated world production of barley in 2005 was around 140 million metric tons (FAO, 2005) and the production generally fluctuates based on global market trends and demands. Of the total production, the Russian Federation produces 12%, followed by Canada and Germany (9% each), France (8%), Ukraine and Turkey (7% each), Australia (5%), UK (4%), US and Spain (3% each), and the remaining from the other countries around the world (FAO, 2005). Barley is generally used as malt for the production of alcoholic beverages and as animal feed. It is also consumed as food in some parts of the world. There is a lot of interest in developing barley for consumption as food and attributes such as starch quality and protein composition and content are being studied. There has also been interest in specialty barleys for industrial applications.

1.4 Traditional Approaches of Crop Improvement

The flowering plants appeared in the middle of the Mesozoic era of the lower Cretaceous period about 150 million years ago, predating the *Homo sapiens*, whose appearance trace back to the quaternary period of the Cenozoic era about 1.8 million years ago. Thus, the flowering plants already had a long evolutionary history and improvement strategies in plant agriculture would date back to the dawn of civilization, when primitive gatherers started identifying quality attributes in plant products and began intentionally propagating them. In fact, besides influencing plant product palatability and ease of harvest, human beings did not have a major

impact on the overall structure of crop plants (Hancock, 2004). Therefore, the improvement brought about by early humans, although based on intuitiveness, could be conceived as the beginnings of some form of conventional plant breeding, which became more organized as a result of more colonial life styles and establishment of homesteads. Fairly well blended into this scheme of plant agriculture evolution is barley as one of the ancient crops. Its share of “directed evolution” from this deliberate propagation of desirable traits is exemplified by a change from brittle rachis forms to nonbrittle forms. It is believed that about 19 000 years ago ancestral humans gathered wild two-rowed barleys with spikes showing shattering disposition and nonshattering forms had started to be cultivated about 9500 years ago in areas such as Netiv Hagdud, north of Jericho, and Abu Hureya (present day Syria) (Zohary and Hopf, 2000). The available gene pool in barley has been fairly wide and sources of genetic variability are potentially available in wild species and landraces. There have been extensive efforts directed toward identification of traits of interest for incorporation into new varieties.

1.4.1 Conventional breeding

Improvement of barley varieties through breeding programs has been multifaceted and has to a great extent been geared toward producer and consumer. However, environmental adaptation for adequate growth and yield has also been given due consideration. Besides development of high yielding varieties as their main objective (Anderson and Reinbergs, 1985), plant breeders have also targeted other characters that affect quality and yield indirectly. With barley, the breeding objectives have been somewhat more elaborate due to the existence of the malting market niche and the feed market, the former being more profitable and therefore, receiving more incentive for improvement by way of funding from malting and brewing industries. In recent years, another dimension has been added to barley breeding efforts to cater to food quality barley of nutritional value. The realization that barley can offer nutraceutical alternatives has had health initiative groups and industry to take advantage of this new market value for barley.

Breeding objectives have thus evolved over the years, with characteristics such as malting quality, protein content, disease resistance, days to maturity, plant height, straw strength, etc. all being considered in some form or the other in addition to keeping up with the dynamic nature of the barley market demands. Breeding methods have, therefore, been structured to meet the intended goals and plant breeders have very successfully adopted a number of the conventional breeding strategies. Further details regarding barley breeding can be found elsewhere (Anderson and Reinbergs, 1985). A number of parameters such as resistance to lodging and disease, reduced height and increase in harvest index have significantly contributed to yield increases (Busch and Stuthman, 1990). Considering the economic returns on malting barley, improved grain quality attributes have targeted increases in grain plumpness, higher malt extract, α -amylase activity, and diastatic power (Wych and Rasmusson, 1983). There has been a general trend among breeders to aim for high malting quality barley varieties during breeding, with a notion that the newly developed variety will also be valuable as feed barley (Kling *et al.*, 2004). The progress in breeding for value-added barley has gained further impetus in recent years with the advent of a variety of DNA-based markers, heralding the concept of marker-assisted breeding. Incorporation of a desirable trait, qualitative or quantitative, into new varieties can now be accomplished reasonably quickly in breeding programs that have embraced a parallel molecular marker-based program.

1.4.2 Mutagenic approaches

Even though breeding efforts have contributed significantly to the release of countless improved varieties, a gradual erosion of genetic diversity has led to a need for the identification of new sources of variability, pre-existing as well as *de novo* generated. Therefore, plant breeders have had recourse to screening for mutations for incorporation of new traits into their breeding programs—a practice eventually termed mutation breeding, which has been around for almost a century. The tobacco cultivar, Chlorina, was the first variety derived from mutagenic x-ray irradiation treatments and was commercially

released in 1934 (Tollenaar, 1934, cited in van Harten, 1998). It was almost two decades later, in 1950 that another commercial variety of mustard, cv. Primex, was released also as a result of x-ray-induced mutations. It should, however, be noted that plant breeders have also used naturally occurring mutants successfully. The green revolution was heralded by the use of dwarfing genes found in a Japanese wheat cv. Norin-10. High yielding dwarf rice varieties with strong straw were derived from spontaneous semi-dwarf mutation phenotype in a rice cv. Dee-geo-woo-gen from Taiwan.

Naturally occurring variability in barley has generally not been an issue for incorporation in breeding programs. However, with the ever-changing demands on barley breeding programs and priorities, alternative sources of variation need to be identified. This need for variability could not be more emphasized than with breeding for resistance to diseases such as the *Fusarium* head blight of barley. Mutation breeding in barley has nonetheless been practiced and a first mutant resistant to powdery mildew was produced by Freisleben and Lein in 1942. As of February 2007, 2454 mutant plant varieties were listed in the FAO/IAEA Mutant Varieties Database, of which 256 were barley varieties (FAO, 2007). Induced mutations in barley were generally aimed toward the development of disease resistant and high grain protein varieties in the past (Gupta, 1998). Traits pertaining to lodging resistance (FAO/IAEA, 1984a, 1988), days to maturity (Gottschalk and Wolff, 1983; Donini *et al.*, 1984; Konzak, 1984), and grain protein content (FAO/IAEA, 1979, 1984b; Micke, 1983; Müeller, 1984) have been modified by mutation breeding. Development of barley resistant to diseases can best be exemplified by the cultivar Heine's Haisa, which is resistant to *Erysiphe graminis* f. sp. *hordei*, the causal agent of powdery mildew and was produced by x-ray irradiation (Micke, 1992). Mutants with improved brewing and malting quality or improved grain protein content have also been produced (FAO/IAEA, 1996). Using barley mutants Lundqvist and Lundqvist (1998) elucidated genetics of spikelet rows. They were able to show that at least 12 gene loci (*hex-v* and *11 int*) were involved in the spike development including the lateral florets, kernel size, awns, and fertility. Considering the number of barley varieties

released as a result of mutation breeding, it is conceivable that barley improvement is likely to be more significantly influenced by mutagenesis in the future. Even though mutation can generate a lot of variability, a large number of nonuseful mutants are also produced. Therefore, a more targeted and controlled method of producing useful mutants would be of value.

Induced mutations can now be specifically targeted for alteration of known genes. This mutation strategy termed TILLING (targeting induced local lesions in genomes) (McCallum *et al.*, 2000) has become an important tool in genomics studies. TILLING is combination of classical chemical mutagenesis and high-throughput molecular biology techniques for the identification of desired mutants. With the TILLING strategy single base pair changes can be identified in a gene of interest (Till *et al.*, 2003). It involves mutagenesis of seeds with ethylmethane sulfonate (EMS), growing plants (M_1), allowing selfing, planting individual M_2 seeds for DNA extraction, and cataloging M_3 seeds (Figure 2). DNA from the M_2 plants is pooled for polymerase chain reaction (PCR) amplification of the gene of interest. PCR products are denatured and upon reannealing heteroduplexes are formed. Originally denaturing high-performance liquid chromatography (HPLC) was used to analyze heteroduplexes for mutations (McCallum *et al.*, 2000). Subsequent modifications included treatment of the heteroduplexes with an endonuclease, *CELI*, which specifically cleaves

mismatches between mutated and nonmutated variant heteroduplexes (Colbert *et al.*, 2001). *CELI*, which was identified in celery, recognizes single base mismatches and cleaves on the 3'-side of the mismatch (Oleykowski *et al.*, 1998). Cleaved heteroduplexes are resolved by electrophoresis for the identification of mutations. The mutant plant is then identified by screening DNA from individual samples constituting the pool. EMS treatment primarily leads to G/C to A/T transitions and such randomly distributed G/C to A/T transitions in *Arabidopsis thaliana* account for up to 99.5% of mutations (Greene *et al.*, 2003). TILLING populations have been produced for *A. thaliana* (Till *et al.*, 2003), *Lotus japonica* (Perry *et al.*, 2003), maize (Till *et al.*, 2004), barley (Caldwell *et al.*, 2004), and wheat (Slade *et al.*, 2005). The wheat TILLING population has led to the identification of a range of *waxy* phenotypes (Slade *et al.*, 2005) and similar barley starch variants could be identified for specialty end uses. Using Eco-TILLING, which is a high-throughput TILLING strategy (Comai *et al.*, 2004), Mejlhede *et al.* (2006) were able to identify point mutations and deletions in the powdery mildew resistance genes *mlo* and *Mla* of barley. Thus, a large number of variants were generated, offering the possibility of combining these novel alleles for studying powdery mildew resistance.

Another approach to targeted mutagenesis is the use of transposable elements. Transposable elements have certain advantages over other approaches for identifying and determining gene function in large genome cereals, like barley. Different strategies have been used to exploit the maize *Activator (Ac)/Dissociator (Ds)* transposon system for targeted mutagenesis in heterologous species. Either large numbers of independent *Ds* insertion lines or transposants (TNPs) are generated and screened for biochemical or physiological phenotypes, or smaller numbers of TNPs are produced, *Ds* locations mapped and the element remobilized for localized gene targeting. Barley cv. Golden Promise was engineered with a *Ds-bar* element and *Ac* transposase (Koprek *et al.*, 2000). The two elements were brought together in the same cell, resulting in transposition of *Ds-bar* to a new location; the reactivation of *Ds* occurred at frequencies of 11.8–17.1% (Singh *et al.*, 2006). Sequence flanking the *Ds* insertion was determined and BLAST searches using a

Figure 2 Schematic of TILLING strategy

gene prediction program demonstrated that 86% of the TNP flanking sequence matched either known or putative genes. Mapping of insertion sites (e.g., Cooper *et al.*, 2004; Singh *et al.*, 2006), coupled with the observed remobilization frequencies of primary, secondary, tertiary, and quaternary TNPs and the tendency for localized *Ds* transposition (~75% frequency), validate a saturation mutagenesis approach using *Ds* to tag and characterize genes linked to *Ds*.

1.4.3 Interspecific and intergeneric crosses

The use of wild species and genera for wide crosses has appealed to plant breeders due to the possibility of identifying traits of value for incorporation in new cultivars. Identification and introgression of genes from wild species of *Hordeum* into cultivated barley have been attempted. The crossability of *Hordeum* species with barley has been very low (Bothmer *et al.*, 1983) and chromosome pairing in the interspecific hybrids has generally been poor, except for hybrids derived from *Hordeum bulbosum* and *H. spontaneum* crosses with barley (Fedak, 1989). Difficulties associated with the production of interspecific hybrids have been reviewed recently and include incompatibility, chromosome elimination, endosperm degeneration, instability of hybrids and chromosome pairing, infertile hybrids, reduced recombination, and linkage drag (Pickering and Johnston, 2005). However, in spite of all barriers, agronomic traits for disease resistance and stress tolerance have been expressed in hybrids or backcross progenies (Fedak, 1985). Intergeneric hybrids have also been possible for barley. The number of intergeneric hybrids produced in combinations of *Secale*, *Agropyron*, or *Elymus* with *Hordeum* species has far exceeded those produced with *H. vulgare* (Fedak, 1989, 1992), and could be due to closer phylogenetic relationships among wild genera within the Triticeae tribe than to domesticated barley. With more research it is likely that many of the innate barriers with regards to wide hybridization would be overcome. Baum *et al.* (1992) have reviewed some of the strategies to overcome these barriers in wide crosses in cereals. One of the contributing breakthroughs in recovering interspecific or intergeneric hybrids has been the use of *in vitro* cultures (see Section 2.1.1).

2. DEVELOPMENT OF TRANSGENIC BARLEY

2.1 Technology-driven Improvement

The worldwide importance of barley for food, feed, and malt demands that efficient methods be developed for the improvement of barley cultivars for enhanced agronomic performance, pest resistance, yield, and quality traits. Such methods can also be applied for diversifying attributes of barley for alternative uses. The use of genomics tools, marker-assisted selection, doubled haploid production, and genetic engineering approaches are all contributing toward this technology-focused improvement. The introduction of information into barley through genetic transformation technologies, as with other crop species, utilizes methods based on the delivery, integration, and expression of specific genes of interest into plant cells that are grown *in vitro*. The success of this approach is dependent on the efficiency of generating independently and stably transformed, fertile, green plants that maintain the important characteristics of the starting germplasm.

Biotechnology has unequivocally become an integral part of barley improvement programs. The access to additional gene pools has become a possibility due to the development of tissue culture and transgene technologies. For a long time, barley was considered to be recalcitrant to both technologies; however, major obstacles have now been overcome. DNA-based markers provided the breeder with another tool to select for desirable traits, thereby enabling more effective selection and also expediting the breeding process. The use of *in vitro* culture for barley improvement has been three pronged, namely, induction of variation, doubled haploid production, and genetic transformation.

2.1.1 *In vitro* culture and somaclonal variation

The availability of an efficient regeneration system is essential for successful tissue culture. Even though barley was fairly recalcitrant to tissue culture, significant progress has been made. The explants used for culture have included immature tissues such as embryos, scutella, inflorescences, ovaries and ovules, anthers, microspores, apical

meristems, mature embryos, and leaf bases. Immature tissues as explants have generally responded better in culture than mature tissues. In recent years, there has been interest in the use of meristematic tissues and mature embryos for culture and these have been shown to efficiently produce multiple shoots directly without an intervening callus phase in response to the plant growth regulator, thidiazuron (Ganeshan *et al.*, 2003, 2006).

The *in vitro* culture system was thought of as a novel approach at identifying variability by subjecting the cell cultures to selection pressure in a manner similar to that employed by breeders. Tissue culture-induced variation referred to as somaclonal variation (Larkin and Scowcroft, 1981) led to further speculation that *in vitro* cultures could generate more genetic variability. As mentioned earlier, the generation of new chromosomal combinations and mutations by way of interspecific and intergeneric hybrids was well recognized. The occurrence of chromosomal variability in callus and plants derived from ovary tissue cultures of a *H. vulgare* x *H. jubatum* hybrid was also observed (Orton, 1980). Thus tissue cultures had started to be perceived as a way for overcoming barriers inherent in conventional gene introgression in breeding. A similar approach was explored with hybrid plants recovered by embryo rescue from a cross between *H. vulgare* x *Elymus canadensis* (Canada wild rye) (Dahleen and Joppa, 1992). Canada wild rye possesses winter-hardy attributes, drought tolerance, and resistance to barley yellow dwarf virus, but F₁ hybrids with barley are sterile and the *in vitro* culture rescued hybrids showed chromosomal recombination. Other earlier studies have reported cultured barley tissues producing plants showing chromosomal rearrangements, aneuploids and polyploids (e.g., Lupotto, 1984; Singh, 1986; Gaponenko *et al.*, 1988; Lühns and Lörz, 1988), and several studies have attempted to capitalize on this tissue culture-induced variation.

In *H. spontaneum*, heritable somaclonal variation was observed, but no aberrant chromosome structures or numbers were observed (Breiman *et al.*, 1987). Barley plants regenerated on medium containing a toxin from the net blotch pathogen of barley were shown to have improved resistance to the pathogen (Hunold *et al.*, 1992). Control plants regenerated from media containing no toxins, however, also exhibited resistance and were most

likely a result of somaclonal variation. Partially purified toxins from *Helminthosporium sativum* (causal agent of spot blotch) were also used in culture media on barley callus and plants resistant to the pathogen were produced (Kole and Chawla, 1993). Barley plants derived from cultures have also been shown to exhibit tolerance to herbicides such as chlorsulfuron (Baillie *et al.*, 1993) and glyphosate (Concepcion-Escorial *et al.*, 1996) in response to culture media containing the respective herbicides.

Even though somaclonal variation has had positive effects, there have been negative effects associated with it. For example, tissue culture-derived malting barley plants showed poor malting quality (Bregitzer *et al.*, 1995). Furthermore there were differences in agronomic performances in a genotype-dependent manner from tissue culture-derived lines (Bregitzer and Poulson, 1995). In the case of protoplast-derived barley plants, evaluation of the progeny in the field did not show any abnormal phenotypes, but some agronomic characters were affected (Kihara *et al.*, 1998). The adverse effects of somaclonal variation have led to the suggestion that identification of useful transformants might be precluded (Bushnell *et al.*, 1998; see also Section 2.1.2.2).

The lack of consensus with regard to the occurrence or nonoccurrence of somaclonal variation indicates a need to reassess perspectives on somaclonal variation in barley. The culture-induced variation could be due to the components of the specialized media being constantly developed to improve efficiency of regeneration from barley. A highly efficient regeneration system may not always lead to production of all normal plants. Due to the low regeneration frequencies in earlier studies it may have been possible that undesirable regenerants did not develop. Many studies have demonstrated that *in vitro* culture-regenerated barley plants were normal, with very low frequencies of somaclonal variants (Karp *et al.*, 1987; Pickering, 1989; Ruiz *et al.*, 1992). It is believed that the barley genome is tolerant to tissue culture conditions or it may be that due to a competitive disadvantage during the regeneration process, aberrant cell lines fail to develop and therefore fewer somaclonal variants are obtained (Karp and Lazzeri, 1992). More recent data involving the *in vitro* culture of barley cv. Golden Promise indicate that callus and plants derived from nontransgenic and transgenic callus

of approximately the same age had varying levels of ploidy variation after performing chromosomal analysis. Nontransgenic plants regenerated after *in vitro* culture had a lower percentage of ploidy variation (0–4.3%), compared to transgenics of which 46% were tetraploid or aneuploid around the tetraploid level (Choi *et al.*, 2000); tetraploid plants had abnormal morphological features. Ploidy determinations were also made on randomly selected cells from callus of immature embryos and the number of tetraploid cells in 1-day and 7-day-old cultures was 2–4%. However, in callus comparable in age to that used for regeneration the percentage of tetraploid cells was 23%, a percentage lower than the number of tetraploid plants regenerated from transformed lines.

2.1.2 Genetic transformation

The first report of recovery of stably transformed fertile plants utilized a model cultivar, Golden Promise, and microparticle bombardment (Wan and Lemaux, 1994). Organized tissues, like immature embryos, were utilized, rather than embryogenic callus or suspension cells, because of problems encountered in barley transformation, which were more marked than those encountered with other cereals, for example, rapid loss of regenerability of *in vitro*-cultured tissue and the increase in the frequency of albinism over time. The ability to introduce DNA directly into organized scutellar cells at the inception of callus formation enabled identification of transgenic callus and the regeneration of plants before regenerability was lost. Despite successful development of transformation methods for model barley cultivars, their utility for improvement of commercial barley cultivars was hampered by certain problems: (a) lack of reproducible transformation systems for commercial cultivars, (b) potential for introducing somatic mutation and heritable changes during *in vitro* culture, and (c) transgene and transgene expression instability.

2.1.2.1 Lack of reproducible transformation systems for commercial cultivars

Initial reports of successful transformation were highly dependent on using particular cultivars,

like Golden Promise, that were amenable to *in vitro* growth and regeneration of fertile, green plants. Despite their utility for developing transformation strategies, the ability to deploy commercial germplasm with useful novel genes to meet urgent needs is hindered by the use of this germplasm. In fact, the barley germplasm forming the foundation of North American breeding programs is different from Golden Promise in virtually every aspect important to commercial production and utilization. The obligatory transfer of transgenes from Golden Promise to unrelated six-rowed germplasm that forms the basis for malting cultivars in the mid-western United States would require multiple cycles of hybridization and selection prior to the utility of the germplasm for commercial deployment. Such a lengthy and costly process is necessary to preserve allelic combinations critical to commercial use.

Problems arose with the transformation of commercial cultivars because frequencies of callus induction were often low with certain cultivars and long-term cultures of barley lose regenerability quickly. To address this difficulty, efforts were made to develop novel tissue culture systems. In general, callus-maintenance medium containing auxin and no cytokinin was used for the long-term tissue culture periods needed for barley transformation (Wan and Lemaux, 1994). This frequently led to tissues with low regenerability. The use of medium containing 2,4-D, 6-benzyl aminopurine (BAP) and higher levels of copper for callus initiation stimulated the formation and maintenance of green, regenerative tissues with long-term regenerability characteristics (Cho *et al.*, 1998). A callus maintenance medium with 2,4-D, BAP and higher levels of copper (DBC2 or DBC3, depending on the genotype) was developed and this medium was used as an intermediate step between callus maintenance and regeneration.

The use of the intermediate step appeared to improve regeneration by allowing the small number of green, totipotent cells to continue proliferating and ultimately to convert the tissue from an embryogenic state into a state that more closely resembled the morphology of a shoot meristem culture. The latter tissue could be triggered to produce multiple shoots. Such tissue was used, with other alterations in the transformation procedure, to transform both Harrington and Galena (Lemaux *et al.*, 1999).

Green, regenerative tissues of Galena, Golden Promise, Harrington, and Salome, were maintained for more than a year on DBC2 or DBC3 and gave rise to fertile, green plants. Morphologically, green tissues look strikingly similar to those derived from excised shoot apices of barley cultured on 2,4-D and BAP (Zhang *et al.*, 1998). Molecular analysis using immunolocalization confirmed visual observations about the meristematic state of the barley tissues and was different from the state of tissue maintained on auxin alone (2,4-D or dicamba). Green regenerative tissues generated and maintained on DBC2 or DBC3 medium were used successfully as transformation targets for Galena, Golden Promise, and Harrington (Lemaux *et al.*, 1999).

Another possible target tissue, similar in some respects to the shoot apical meristem, is *in vitro*-derived shoot meristems. These cultures derive from shoot apices of barley (Zhang *et al.*, 1998) and other cereals and they arise from the shoot apex by culturing the tissue on auxin- and cytokinin-containing media. This medium arrests the development of the shoot apical meristem and allows proliferation of axillary meristems from which adventitious meristems develop. DNA is introduced into the cells of the proliferating adventitious meristems and by culturing under selection nonchimeric, transformed plants were generated from barley (Zhang *et al.*, 1999). *In vitro* shoot meristematic cells are fundamentally different because they proliferate from pre-existing meristematic cells in the axillary meristems (Zhang *et al.*, 1998), which undergo little or no dedifferentiation. Proliferation appears to require only a simple redirection of cells in the shoot meristem, not a dedifferentiation as occurs with cells in the immature scutellum or microspore.

2.1.2.2 Potential for introducing somatic mutation and heritable changes during *in vitro* culture

Plants from *in vitro* culture frequently accumulate heritable genetic changes, which can result in moderate to severe negative changes in important agronomic and biochemical characteristics. The elements of the *in vitro* environment causing these changes correlate with specific facets of the transformation process (Choi *et al.*, 2001)—the

most important of which is the selection process. The means by which the *in vitro*-cultured tissue is established also has an impact on regenerability but is minor relative to the other factors. Somaclonal variation, the accumulation of genetic and epigenetic changes, hinders the regeneration of fertile, green plants and their subsequent use as parents in a breeding program.

In barley, analysis of the agronomic performance of nontransgenic tissue culture-generated plants and transgenic barley plants showed significant somaclonal variation for important determinants of agronomic performance and the impact varied with the tissue culture and transformation methods (Bregitzer *et al.*, 1998). Although backcrossing can usually eliminate these problems, this requires additional time and effort and will be problematic if the induced mutations are closely linked to the transgene(s). An unexpectedly high percentage of somaclonal variants (14–60%) were shown to be present among progeny of transgenic barley plants evaluated in the field (Bregitzer *et al.*, 1998). The report also shows that somaclonal variation was accentuated by the transformation procedure. This supposition is based on chromosomal analyses of callus and plants from *in vitro*-cultured nontransgenic and transgenic barley lines (Choi *et al.*, 2000; see also Section 2.1.1). A higher percentage (78%) of karyotypically abnormal cells was observed in transgenic barley callus cultures, compared with 15% of cytologically abnormal cells in nontransgenic callus and aspects of the transformation process, i.e., osmotic treatment and selection pressure, appeared to have triggered the cytological abnormalities (Choi *et al.*, 2001).

2.1.2.3 Transgene and transgene expression instability

One limitation of current transformation methods is that insertions occur randomly and insertion location might not be optimal for gene expression. This has been noted in plants derived from *Agrobacterium*-mediated methods as well as microparticle delivery. Another problem, more common with microparticle methods, is that introduced DNA is usually present in multiple, tandemly arrayed copies. Having multiple copies of the introduced genes, closely linked and in

inverted orientation can lead to gene inactivation and genetic instability. While position effects and multicopy-induced gene silencing occur, they are not the only mechanisms of transgene silencing. For example, neither the presence of tandemly arrayed copies of the transgene nor position effects completely explain variability in expression among progeny derived from the same parent (e.g., Meng *et al.*, 2006) (see Section 2.4).

2.1.3 Doubled haploid technology

Doubled haploid breeding technology has been widely adapted in barley breeding programs. The fact that homozygosity can be achieved in one generation by chromosome doubling after haploid plant production allows for advanced generation breeding within a short time. The doubled haploid breeding approach allows breeders to decide on the number of cycles of recombination to allow before homozygosity is attained, since doubled haploid plant can be initiated at any stage during the breeding process (Snape and Simpson, 1981; Choo, 1985).

Methods for producing haploids in barley include the bulbosum technique, haploid initiator gene method, ovary, anther, and microspore culture. Several reviews have been published on haploid production and use in barley breeding (e.g., Choo, 1985; Kasha and Ziauddin, 1990; Pickering and Devaux, 1992; Forster and Powell, 1997). The bulbosum method was a result of wide hybrids between *H. vulgare* x *H. bulbosum*, wherein upon embryo rescue the regenerated plant was found to be haploid (Kasha and Kao, 1970). Since this method has been adaptable to a number of barley genotypes, its use has been widespread in the past (Kasha and Reinbergs, 1981). An induced mutation in barley has led to the identification of a haploid initiator gene (*hap*), which leads to haploid barley plants (Hagberg and Hagberg, 1980). The advantage of the *hap* gene is that recourse to a tissue culture system is not necessary, but there has been difficulty in distinguishing between spontaneous doubled haploids and hybrid embryos (Forster and Powell, 1997). Furthermore only genotypes possessing the *hap* gene can be used with this method (Forster and Powell, 1997).

Due to the potentially large numbers of plants that can be regenerated using the anther and microspore culture techniques, the latter

have become very popular. However, androgenic cultures require very delicately optimized conditions for high regeneration efficiency. The growth conditions of the donor barley plants and physiological state of the anthers play important roles in responsiveness. Plants obtained from androgenic cultures have shown genetic instability and genotype dependency, but due to extensive research efforts these drawbacks have been overcome. Segregation distortion ratios observed in doubled haploids from androgenic cultures still need to be understood (Foroughi-Wehr and Friedt, 1984; Powell *et al.*, 1986; Thompson *et al.*, 1991). Irrespective of these problems, doubled haploids derived from androgenic cultures have been extensively used in barley breeding programs, surpassing the bulbosum method (Forster and Powell, 1997).

The doubled haploid barley breeding program has been very successful and has led to the release of a number of improved varieties. It has been suggested that true-to-the-type mutants could be generated using mutagenesis in conjunction with haploid production (Maluszynski *et al.*, 1995). Several doubled haploid barley mutants have been obtained using this approach (Umba *et al.*, 1991). The barley haploid production scheme can also be used for genetic transformation and microspores had been suggested to be attractive targets for this purpose (Ziauddin *et al.*, 1990), and there are a number of reports pertaining to this possibility. Microspores transformed by electroporation have been shown to transiently express a gene of interest (Kuhlman *et al.*, 1991). Transient *GUS* gene expression was also demonstrated in barley microspores transformed by particle bombardment (Yao and Kasha, 1997). Stable transformants derived from microspore transformation have also been obtained (e.g., Harwood *et al.*, 1995). More recently Kumlehn *et al.* (2006) successfully produced stable barley transformants by infection of androgenetic pollen cultures with *Agrobacterium tumefaciens*.

2.1.4 Spike culture and antisense oligodeoxynucleotide technology

This culture system was recently optimized specifically for following the starch biosynthesis pathway during grain development in cereals from preanthesis to maturity under defined and

Figure 3 Diagrammatic representation of cereal spike culture establishment. (a) Immature spike is excised just above the soil surface when about a centimeter of the awns is visible. (b) All the leaves are removed and the spike is placed in a sterile culture medium after cutting a few millimeters from its base. The liquid medium consists of sucrose and L-glutamine and is replaced every 4 days, at which time a few millimeters are cut from the base of the spike before placing it back into the fresh medium. (c) Anthesis occurs after about 7 days in culture and maturity is attained in about 30 days

controlled conditions (Figure 3) (Chibbar *et al.*, 2005). Grain development studies have generally been conducted in growth chambers or field. However, due to a number of uncontrollable variables under these conditions, changes in starch accumulation patterns can be confounding. It is, therefore, difficult to assign cause and effect. The immature spike culture is established at a stage prior to anthesis and thus, postanthesis changes can be followed up to maturity, which is attained within about 30 days from culture initiation. The culture medium being simple, allows for targeted supplement of desired chemical stimuli or other factors for monitoring their effects on starch biosynthesis. Using quantitative real-time PCR the expression patterns of the genes involved in starch biosynthesis can be studied. The antisense oligodeoxynucleotide (ODN) technology can also be used with the spike culture system for the suppression of specific starch biosynthetic genes and to observe the effects on starch accumulation (Jansson *et al.*, 2007). The possibility of suppressing expression of genes using short antisense ODNs was first demonstrated in 1978 (Stephenson and Zamencnik, 1978; Zamencnik and Stephenson, 1978). Naturally occurring antisense ODN suppression of gene expression has

also been reported in prokaryotes and eukaryotes as a defense mechanism against viral infection (Vanhee-Brossollet and Vaquero, 1998; Lehner *et al.*, 2002). The antisense ODN technology has been extensively explored for therapeutics as a means of drug delivery and also for fundamental gene silencing studies in humans and animals (Shi and Hoekstra, 2004). The use of the antisense ODN technology in plants has not received the same fervor as with mammalian systems. The earliest report of antisense ODN in plants was demonstrated using barley aleurone to suppress the expression of α -amylase (Tsutsumi *et al.*, 1992). The other report used excised barley leaves to understand the role of a sugar-inducible transcription factor, SUSIBA2, in the regulation of starch synthesis (Sun *et al.*, 2005).

2.1.5 Genetic engineering approaches

The success of transformation technology in barley relies upon the availability of a suitable DNA delivery system, transformation-competent target cells, tissues or organs, and an efficient *in vitro* regeneration system. Ideally, an *in planta* transformation system would be desirable as it would eliminate the tissue culture regeneration steps. For example, injection of DNA from a two-row barley plant into developing seeds of a six-row waxy barley was attempted (Soyfer, 1980) and some plants with normal starch composition and two-row phenotype were observed, but there was no Mendelian segregation. Mendel *et al.* (1990) injected plasmids carrying the *NPTII* gene into floral tillers of barley and applied plasmid DNA to stigma, but were not successful. Brettschneider *et al.* (1990) inoculated florets at anthesis with *Agrobacterium* with no success. Attempts at DNA uptake by germinating seeds (Ledoux and Huart, 1969) and imbibition of embryos in DNA suspensions (Töpfer *et al.*, 1989) have also been unsuccessful.

Attempts have also been made at delivering DNA by microinjection and electroporation. Microinjection appears to be a very suitable system, but requires highly specialized and expensive resources, besides skills. Furthermore, the delivery of the DNA has to be precise to minimize damage to the cells. The low number of cells that can be injected implies that regeneration frequency needs to be high with respect to

the microinjected cells to generate putative transformants. Cells that would be ideal targets for microinjection include proembryos from zygotes and those derived from cultured microspores (Karp and Lazzeri, 1992). However, with recent successes in high regeneration frequencies from barley microspores, microinjection could become a potentially useful transformation approach again. As an alternative to microinjection, electroporation had gained widespread attention. Although initially barley protoplasts were thought as ideal targets for electroporation and used for transient expression assays (e.g., Teeri *et al.*, 1989; Salmenkallio *et al.*, 1990), cells and tissues have also been used subsequently. For example, Gürel and Gözükmizi (2000) used mature barley embryos for electroporation and produced stably transformed plants. Many of the studies using protoplasts also employed PEG to enable DNA uptake (e.g., Junker *et al.*, 1987; Lee *et al.*, 1991). The limitations of barley protoplasts as targets for transformation include viability of protoplasts for culture (especially after transformation), genotypic dependency, labor-intensive protoplast isolation procedure, and loss of morphogenic potential after extended culture duration (Lütticke *et al.*, 1996). Protoplasts are also prone to somaclonal variation and it has been suggested that barley protoplasts be isolated from primary callus tissue obtained from immature young scutella, microspores, or anthers to avoid regeneration problems (Stödt *et al.*, 1996).

The method of choice for the transformation of barley has been the microprojectile bombardment, in spite of its harsh nature. Since the first report of stably transformed barley plants using this method (Wan and Lemaux, 1994), there have been many reports and reviews regarding principles and parameters for barley transformation (Lemaux *et al.*, 1999; Klein and Jones, 1999; Horvath *et al.*, 2002). Optimization efforts are continually being conducted in various laboratories to improve the barley transformation efficiency further. The random insertion of the transgene into the genome has been a subject of interest, with issues such as transgene integration at multiple sites, rearrangements, truncations, gene stability, and expression (Båga *et al.*, 1999). In order to simplify integration patterns, remove selectable marker genes and decrease the amount of *in vitro* culturing needed to generate large numbers of

independent events, the *Ds* transposable element system was used as a gene delivery vehicle (Koprek *et al.*, 2000). A gene of choice was engineered between *Ds* inverted-repeat ends, introduced into barley by bombardment, reactivated by exposure to *Ac* transposase, and the transposed element carrying the gene of choice segregated away from transposase to stabilize its chromosomal location. Gene delivery via *Ds* was shown to dramatically increase gene expression stability (Koprek *et al.*, 2001; see also Section 2.4).

While the use of the microprojectile bombardment for barley transformation continues to be used and debated, in recent years the ability to use *Agrobacterium* for barley transformation has become a reality (Tingay *et al.*, 1997; Guo *et al.*, 1998; Wu *et al.*, 1998). Due to its simplicity, cost effectiveness, and fewer manipulative steps, this method of transformation has wide interest. However, optimization for routine transformation is still time consuming.

In the preceding paragraphs, transformation methods were alluded to with little emphasis on the tissue culture regeneration systems. As important as the DNA delivery system is for efficient barley transformation, the recipient cell or tissue is also important, specifically with regards to regeneration efficiency. There have been numerous reports on optimization approaches for improving the regeneration frequency in barley. Immature scutella have generally been used due to their responsiveness in *in vitro* culture. However, due to the time-consuming and labor-intensive isolation process, alternative sources of explants have been sought. Furthermore, the donor plants have to be grown under optimal conditions in carefully controlled growth chambers to ensure optimum response in culture. Callus derived from young leaf tissues has also been tested (Mohanty and Ghosh, 1988; Pasternak *et al.*, 1999), but due to limited success there has been a lack of widespread interest. More recently, Ganeshan *et al.* (2003) have reported the use of leaf-base/apical meristems with limited regeneration efficiency, but showed the use of mature embryo as more suitable explants for efficient regeneration from barley. The use of mature embryos and apical meristems as explants for *in vitro* regeneration is very appealing due to the ease of isolation. Callus induction and regeneration from mature embryos of barley was reported as early as 1984 (Lupotto, 1984) and from

isolated apical meristems as early as 1975 (Cheng and Smith, 1975). Circumvention of a callus phase and direct induction of shoots from such mature embryos and apical meristems have a definite advantage since somaclonal variation associated with the callus phase could be obviated. Using such meristematic tissues, transformed barley plants have been produced (Zhang *et al.*, 1998, 1999). More recently mature embryos have also been induced to produce multiple shoots directly and shown to be transformation competent (Ganeshan *et al.*, 2003, 2006; Ganeshan and Chibbar, unpublished). It is the development of specialized media that has led to the high frequency of regeneration in a fairly genotype-independent manner from mature embryos. The mature embryo also has the advantage that there is no requirement for the growth and maintenance of donor plants for explant isolation. Mature embryos can be readily isolated from mature seeds, including those obtained from field-grown plants. With respect to winter cereals, the need for vernalization prior to obtaining immature explants is also eliminated. Thus, the mature embryo culture offers a simple, efficient, and expedited culture system. Explants such as immature ovaries, immature inflorescences, and anthers/microspores have also been explored for use as targets for barley transformation. Transgenic plants from barley microspores have been reported using microprojectile bombardment (Jähne *et al.*, 1994; Yao *et al.*, 1996).

2.1.6 RNAi technology

The production of loss-of-function mutants by induced mutations, insertional knockout, and antisense down-regulation has been achieved in many plants, with *A. thaliana* being a classical example. Generally, production of such mutants is time consuming, resource demanding, and often leads to undesirable changes, especially in plants with complex genomes. More recently, the RNA interference (RNAi) technology has been viewed as a viable alternative for gene silencing. Unlike the antisense ODN, RNAi technology can allow stable silencing of genes. RNAi-mediated gene silencing occurs post-transcriptionally as a result of double-stranded RNA. It was first reported in the nematode worm, *Caenorhabditis elegans* (Fire *et al.*, 1998) and was also demonstrated in

plants (Waterhouse *et al.*, 1998). RNAi has down-regulatory potential which can be directed to the gene of interest and would be valuable in complex genomes like barley and wheat for studying both genes involved in biosynthetic processes as well as for targeting changes in *in planta* product synthesis.

Requirements for the establishment of RNAi technology in plants include availability of a transformation system and design of transgene constructs so that transgenes produce hairpin RNAs (hpRNA) with double-stranded RNA (dsRNA) regions (Waterhouse and Helliwell, 2002). Studies have been conducted to determine if RNAi technology would be useful for reverse genetics or for alteration of starch in model plants. In tobacco plants, Chen *et al.* (2005) showed that transgenic tobacco lines produced by RNAi accumulated 3–5 times more starch than nontransformed plants when the gene coding for sucrose-6-phosphate phosphatase was silenced. Sucrose-6-phosphate phosphatase converts sucrose-6-phosphate to sucrose. In transgenic *Arabidopsis* plants, RNAi-mediated silencing of β -amylase8 led to starch accumulation in the leaves, in the presence or absence of a cold treatment (Kaplan and Guy, 2005). Temperature stress induces β -amylase accumulation, which leads to an increase in maltose content and is a protective mechanism for membrane proteins and the electron transport chain (Kaplan and Guy, 2004). More recently by RNAi-mediated silencing of two starch branching enzyme II isoforms (SBEIIa and SBEIIb), Regina *et al.* (2006) produced high-amylose wheat, with some lines showing more than 70% amylose content. The resistant wheat starch produced in this manner was shown to improve large bowel indices in rats and can potentially be of use for designing healthy starches for human consumption (Regina *et al.*, 2006). The RNAi technology therefore opens new possibilities for tailoring starch in barley as well. Due to the diploid nature of the barley genome, application of RNAi-mediated gene silencing should be attainable. In transient assays in barley aleurone cells, Zentella *et al.* (2002) demonstrated that the RNAi silencing of the transcription factor, GAMyb led to a significant reduction in gibberellin (GA)-induced α -amylase. In another transient RNAi assay, Douchkov *et al.* (2005) assessed functionality of defense-related genes in barley epidermal cells. Thus, silencing

of desired traits in barley by RNAi technology is possible and is likely to contribute tremendously both in gene function analysis and gene targeting in the near future.

2.2 Altered Traits in Barley

2.2.1 Quality

There are many aspects to barley quality. Barley grain is used for human food and animal feed. Barley malt is used for brewing and human food. Barley straw has many uses in animal production and several novel applications in controlling odors and algal production in urban and municipal ponds. Transgenic research to improve barley quality has focused on enzymes needed to breakdown endosperm components, to make more nutrients available for yeast in brewing and for monogastric animals. Research to improve amino acid and mineral composition has just begun and is likely to expand as more genes become available for important nutritional components (Table 2).

2.2.1.1 Malting

Much of the transgenic research for malting barley has emphasized the enzymes involved in malting that help to modify the endosperm. These enzymes are generally irreversibly inactivated at higher temperatures ($>55^{\circ}\text{C}$), which can result in incomplete degradation of the targeted cell components. Three papers describe the insertion and testing of thermotolerant glucanases to help break down glucans and cellulose in the germinating seed. Jensen *et al.* (1996) examined the effects of a hybrid (1,3-1,4)- β -glucanase from *Bacillus* species that had been codon optimized based on preferences found in the native barley version of the gene. Stably transformed plants and their progeny expressed the thermotolerant enzyme. Horvath *et al.* (2000) expanded on this work by placing the hybrid gene and the codon-optimized gene under the control of the **D**-hordein (*Hor3-1*) gene promoter. The highest (1,3-1,4)- β -glucanase expression was obtained with the codon-optimized gene, the **D**-hordein promoter and a signal peptide targeting the enzyme to the vacuoles.

The increased thermostability of the enzyme may not only be useful for malting but the enzyme also survives processing into feed pellets, allowing barley to be fed to poultry by reducing the viscosity of the feed in the intestine and increasing nutrient availability. In the third study, Nuutila *et al.* (1999) report the insertion of a thermotolerant endo-1,4- β -glucanase from *Trichoderma reesei*, under the control of a hybrid high-pI α -amylase promoter. The transgene was expressed during germination and the enzyme retained activity after 2 h at 65°C . The enzyme was produced in quantities that should be sufficient to reduce wort viscosities.

Another important group of enzymes in malting barley is the amylases, which help in break down of starches, providing simple sugars for brewing. These enzymes show similar thermoinactivation as the glucanases. Yoshigi *et al.* (1995) created multiple recombinant barley β -amylases with individual amino acid replacements. One mutant with seven replacements showed an 11.6°C increase in thermostability. Kihara *et al.* (2000) transformed barley with this thermostable β -amylase gene under the control of the native gene promoter and intron. Progeny tested for β -amylase showed transgene enzyme activity was not inactivated until treated at 70°C , while the native enzyme was inactivated at 60°C . Stable transgene expression was confirmed through the T₄ without suppression of the native β -amylase gene. Another malt enzyme manipulated in transgenic barley is α -amylase. A thermostable *Bacillus* α -amylase alkBA, under the control of the barley high-pI α -amylase promoter was used by Tull *et al.* (2003) to develop transformed plants. Overall α -amylase activity was increased 30–100% in T₁ grain but transient expression studies of this enzyme showed reduced thermostability in protoplasts, decreasing its utility in improving malt modification. Increased α -amylase activity may have implications in preharvest sprouting.

One transformation study has attempted to manipulate grain hardness, as softer grains generally have better malting quality and harder grains may provide better feed nutrition. Zhang *et al.* (2003) expressed the maize (*Zea mays* L.) γ -zein protein under the control of the endosperm-specific wheat Glu-1D-1 promoter in transgenic barley. The transgenic grain was heavier and more plump, containing more nitrogen in the form of increased prolamine protein. Approximately 4% of

the total prolamine consisted of the γ -zein trans-protein, but this did not significantly affect grain hardness or vitreousness. It is likely that much higher expression levels would be needed to see any effects in barley as soft maize cultivars contain 15–54% γ -zeins and hard maize contains 14–21% γ -zein.

2.2.1.2 Nutrition

Several studies have examined transformation technology to improve nutritional aspects of barley as food or feed. Barley, like most grains, is deficient in the amino acids lysine and threonine, reducing food and feed quality. Brinch-Pedersen *et al.* (1996) inserted lysine feedback insensitive forms of aspartate kinase and dihydrodipicolinate synthase into barley from *Escherichia coli*. Increased activity of these enzymes provided a twofold increase in lysine, arginine, and asparagines while reducing proline levels in half in T₀ and T₁ seeds. Leaves showed significant changes in amino acid composition with as much as a 16-fold increase in free lysine. These results show promise in manipulating barley amino acid content to meet specific nutritional requirements.

Improving mineral nutrition was tested by Ramesh *et al.* (2004) who inserted an *A. thaliana* zinc transporter (*AtZIP1*) into barley. T₂ lines showed an increase in zinc uptake and transport after zinc deprivation. Seeds from T₂ plants grown under standard conditions showed significantly increased zinc, iron, and magnesium, but seeds were smaller than those of wild-type Golden Promise. Individual transgenic seed still had higher zinc content than individual wild-type seed, showing the potential of transgenics to provide essential minerals.

Transformation efforts also have looked at improving feed use of barley. High levels of arabinoxylans and β -glucans can limit the use of barley as feed for monogastric animals. Feed enzymes, such as xylanases, are often added to feed at higher costs to producers. Patel *et al.* (2000) looked at the practicality of producing these enzymes in barley. They inserted a modified xylanase gene from the fungus *Neocallimastix patriciarum* controlled by the seed-specific promoters from the rice glutenin-B1 or barley B-1 hordein gene (*Hor2-4*). Transgenic

plants showed low levels of endosperm-specific expression through the T₂ and the protein was stable in the seed after storage for 3 months. A codon-optimized form of the xylanase showed increased expression in transient assays and would likely provide increased activity in stable transformants. The research by Horvath *et al.* (2000) described above in the malting quality section provides a thermotolerant glucanase that also would be useful in animal feed. Xue *et al.* (2003) generated transgenic barley expressing a hybrid cellulase (1,4- β -glucanase) that can degrade both cellulose and 1,3-1,4- β -glucans. The codon-optimized hybrid enzyme was expressed at high levels in the endosperm under the control of the rice GluB-1 seed storage protein promoter. The enzyme retained activity in T₂ transgenic grain after 1 year of storage, providing a stable source for this feed enzyme at much lower costs than producing the enzyme by traditional microbial fermentation techniques.

One study attempting to manipulate carbon metabolism examined the SnRK1 protein kinase sequence (Zhang *et al.*, 2001). This sequence has been shown to be involved in sucrose synthesis using antisense constructs in potato. A chimeric antisense construct was created combining sequences from barley seed SnRK1a and SnRK1b, with the transgene targeted to the endosperm by the wheat Glu-1D-1 promoter. Transgenic T₀ plants were recovered and confirmed by Southern blot hybridization, but none of the T₁ plants contained the transgene sequences. Further examination showed the Glu-1D-1 promoter allowed some antisense SnRK1 expression in anthers, causing abnormal pollen development. The 50% of the pollen containing the construct were nonviable, probably from inability to use sucrose, preventing transmission of the transgene. A promoter that does not allow expression in anthers will be needed to manipulate expression of SnRK1 in barley seed.

2.2.2 Disease resistance

Some of the first transformation efforts in plants involved inserting coat protein genes from viruses to induce resistance (Beachy *et al.*, 1990). This was also true in barley as Wan and Lemaux (1994) reported transformants containing the marker

genes *bar* and *uidA* in addition to the coat protein (*cp*) gene from barley yellow dwarf virus (BYDV) serotype PAV. Their success was expanded by McGrath *et al.* (1997) who transformed and tested plants with the coat protein gene from BYDV isolate P-PAV. T₁ plants and T₂ progeny containing the *cp* gene were identified as highly resistant after inoculation with viruliferous aphids. More recently, Wang *et al.* (2001) designed a hpRNA construct that contained BYDV-PAV C-terminal polymerase sequences. Nine of the barley lines developed with this construct showed extreme resistance to BYDV-PAV. Further tests of progeny of two lines showed single gene inheritance correlated with resistance.

A strategy being used to engineer fungal disease resistance is to use plant genes that have shown antifungal activity or that are induced by fungal attack. These can include phytoalexins and various pathogenesis-related (PR) genes like chitinases and glucanases. Leckband and Lörz (1998) transformed barley with the stilbene synthase gene (*Vst1*) from grape (*Vitis vinifera* L.) to produce the phytoalexin resveratrol. This gene is induced upon pathogen attack in several plant species, so the native promoter was used in addition to an enhancer sequence. They showed that the promoter was induced by rubbing leaves with sand and inoculation with the biotrophic fungus *E. graminis*. Inoculation of leaves with *Botrytis cinerea* showed resveratrol was effective in providing resistance. Chitinases and thaumatin-like proteins (tlp) are PR proteins with effects on fungal cell walls and membranes. They have been used successfully in many species to increase fungal resistance. Recently, barley was transformed with a combination of a chitinase and tlp from rice (*Oryza sativa* L.) and the co-expression examined (Tobias *et al.*, 2006). One line showed stable expression of both genes while two other lines lost the chitinase gene while still expressing the tlp. Disease testing of these lines is underway which will provide a comparison of overexpression of tlp alone and in combination with chitinase. Another gene implicated in the hypersensitive response and gene regulation during pathogenesis is lipoxygenase (LOX; Weber, 2002). Overexpression of *LOX2* in transgenic barley using constitutive promoters increased plant senescence, supporting a role for LOX in programmed cell death (Sharma *et al.*, 2006).

Two transformation projects have targeted mycotoxin production resulting from *Fusarium* head blight (FHB) in barley. The first of these (Manoharan *et al.*, 2006) used a *Fusarium sporotrichioides* gene *Tri101*, an acetyl transferase gene that modifies trichothecene mycotoxins to a less toxic form. Unfortunately expression of the enzyme had little effect on *Fusarium graminearum* infection in transgenic plants and the contamination of grain with its main mycotoxin, deoxynivalenol (DON). The second gene inserted was the *PDR5* gene from *Saccharomyces cerevisiae*, an ABC transporter gene that pumps trichothecene mycotoxins from cells (Manoharan and Dahleen, unpublished). Again, the gene had no effect on FHB or DON. While DNA and RNA were present in *PDR5* transformants, no effective activity assay could be found for this membrane-bound protein so it is not known if the enzyme was functional.

As isolation of resistance genes from plants expands, transformation is being used for functional verification of candidate resistance genes. One of the first of these was the stem rust resistance gene *Rpg1* (Brueggeman *et al.*, 2002), which has provided barley with durable resistance to *Puccinia graminis* f. sp. *tritici* for more than 60 years. Horvath *et al.* (2003) transformed the genomic clone of *Rpg1* from the resistant cultivar Morex into the susceptible cultivar Golden Promise. Interestingly, the transgenic Golden Promise lines showed a higher level of resistance than found in the original sources of *Rpg1*, Chevron, and Peatland. Only one copy of the gene was necessary for resistance. When the maize gene *Rp1-D* for resistance to common leaf rust (*Puccinia sorghi*) was inserted into barley (Ayliffe *et al.*, 2004), no novel resistance was acquired. Instead, this maize gene showed aberrant RNA processing, with transcripts lacking the gene's leucine-rich repeat. The resulting truncated transcripts were ineffective, containing only the nucleotide-binding site. Another candidate gene verified by transformation was an eukaryotic translation initiation factor Hv-*elF4E* for *rym4* barley yellow mosaic virus resistance (Stein *et al.*, 2005). This recessive resistance gene was overcome when Hv-*elF4E* sequences from a susceptible cultivar were transformed into a *rym4* resistant near-isogenic line. The transgenic line had dominant susceptibility to barley mild mosaic virus, showing

that variation in Hv-eIF4E sequences control the response to these viruses.

2.2.3 Other traits

Several other genes have been inserted into barley for various purposes. Using the naturally occurring redox protein, *thioredoxin h*, transformants were developed to examine its role in regulating seed storage protein degradation. The wheat *trxh* gene was expressed in endosperm under the control of the B₁-hordein promoter, with highest expression levels when targeted to the protein bodies using a signal peptide sequence (Cho *et al.*, 1999). Transgenic lines over-expressing *thioredoxin h* up to 30-fold showed increased pullulanase activity by an unknown mechanism. Pullulanase is a starch debranching enzyme that hydrolyzes α -1,6-linkages in amylopectin during germination and seedling development. In addition, Wong *et al.* (2002) showed that these same transgenic lines, relative to null segregant lines, had (i) an accelerated germination rate by one day, (ii) an accelerated appearance of α -amylase activity by 1 day, (iii) a 35% increase in the abundance of -SH groups in the hordein I fraction, and (iv) an increase in extractable and soluble proteins—resulting in a shift of protein from the insoluble to the soluble fraction. Kim *et al.* (2003) examined the same transgenic plants for their effects on germination in high selenite concentrations. Not only was germination of seed expressing *thioredoxin h* higher on 2 mM selenite than in null control plants, the transgenic plants converted the selenite to selenomethionine, selenate, and elemental selenium. It is possible that the capability to grow and incorporate selenium in these plants could be exploited to clean up selenium-polluted environments.

Other chemicals besides selenium pollute soils worldwide. One of these is aluminum, which is often solubilized in acid soils, inhibiting plant growth. Delhaize *et al.* (2004) engineered barley to express the wheat *ALMT1* gene, a malate transporter that provides aluminum tolerance. High levels of constitutive expression conferred by the maize ubiquitin promoter allowed robust root growth in the presence of aluminum concentrations that severely inhibited nontransgenic root growth, in both hydroponic culture and in

acid soils. Aluminum tolerance in these transgenic lines was comparable to the tolerance in the wheat cultivar that was the source of *ALMT1*.

Transformation has been used to examine the expression of the maize homeobox gene *knotted1* (*kn1*) in barley (Williams-Carrier *et al.*, 1997). The *kn1* gene, which is required for maintaining indeterminacy and preventing cellular differentiation, is homologous to the barley *Hooded* locus, which causes ectopic meristems to form on the upper lemma and awn. Ectopic expression of *kn1* in the barley awn caused the development of ectopic meristems that formed inflorescence-like structures. Patterns of gene expression in the transgenic lines constitutively expressing *kn1* were very similar to the expression of the native *hvknox3* in awns of *Hooded* mutants. Transformation has been a useful tool to examine expression of potential gene homologs and to compare the underlying mechanisms in monocots and dicots.

2.3 Gene Source and Constructs

With extensive research having been done on producing efficient barley transformation systems, there was eventually an apparent void in deciding genes of specific value for use in barley transformation and also the necessary construct design for temporal or spatial expression of the transgenes. This void appears not to be due to a lack of knowledge base in these areas, but rather due to ill defined or uncertain priorities when it came to barley transformation. Furthermore, with the polemic surrounding genetically modified plants (see Section 2.8) there is a hesitance to investing in genetically modified barley, especially for malting purposes due to fear of nonacceptance. To compound matters further, barley genome sequence information available was limited until recently. While plant genomes like those of *Arabidopsis* and rice have been fully sequenced, such sequence information for barley is now only starting to become available. This has mostly been due to the large size of the barley genome and the presence repetitive sequences. The size of the barley genome is about 5.5×10^{-12} g (Bennett and Leitch, 1995) and contains about 76% of repetitive DNA (Flavell *et al.*, 1974). Nonetheless extensive progress has been made, mainly as a result of more high-throughput genome analysis tools such as

large insert libraries, automated sequencing, and data mining being available. The United States Department of Agriculture (USDA) CSREES-sponsored Barley Coordinated Agriculture Project (Barley CAP; <http://www.barleycap.org>) is developing a 3000 single nucleotide polymorphism (SNP)-based genetic/physical/expression map of the barley genome. The project will develop The *Hordeum* Toolbox, which will serve as a public resource for the dissemination of large SNP data sets that relate to genetic, phenotypic, and trait data, and utilize resulting information to develop elite barley germplasm using high-throughput marker-assisted selection.

2.3.1 Gene isolation

Forward genetics and reverse genetics are essentially the two approaches available for gene isolation, i.e., eventually leading to assignment of function to DNA sequence information. While forward genetics proceeds from phenotype to gene following the classical Mendelian patterns of segregation, reverse genetics relies on available sequence information, be it genomic DNA, cDNA (complementary DNA), or protein, and proceeds toward phenotype/function assignment. Forward genetics has evolved to encompass molecular markers for the generation of saturated maps, enabling “tagging” of candidate genes of interest. Further narrowing the gaps between the candidate genes and the markers by fine mapping followed by physical mapping, subsequently leads to the possibility of isolating the candidate gene. This gene isolation strategy by map-based cloning has been successful in a number of plants (see Zhang, 2007 for a review). In barley, it has been very useful in the isolation of disease resistance gene analogs (RGAs). For example, by

positional cloning based on barley–rice synteny mapping, Collins *et al.* (2003) were able to isolate the *ror2* gene, which confers resistance to powdery mildew. Recently a translation initiation factor 4E conferring resistance to Bymovirus was also isolated by map-based cloning (Stein *et al.*, 2005). It is interesting to note that most of the map-based cloning approaches in barley have targeted disease resistance genes (Table 3).

The generation of mutant phenotypes by T-DNA insertional mutagenesis or transposon tagging or gene silencing can be of value for mapping and map-based cloning. The availability of TILLING and *Ds* tagging populations in barley could further expedite map-based cloning approaches. Furthermore, in addition to the isolation of genes, there is a need to isolate regulatory sequences to better understand control of gene expression. For example, in barley understanding the temporal and spatial expression patterns of key genes involved in germination would lead to better control of germination for production of good quality malt. It is known that in malting barley, breeding for high enzyme production is highly desired to obtain good malt and by overexpressing the *HvGAMYB* gene in barley, it was shown that the GA-induced amounts of hydrolytic enzymes were increased in germinating grains (Murray *et al.*, 2006). This study iterates the importance of understanding gene function and with regards to barley, besides disease resistance gene understanding, functions of those involved in quality attributes need to be elucidated.

2.3.2 Chimeric vector construct and special designs

The construction of chimeric vectors with specific promoters, enhancer elements, intronic sequences,

and matrix-attachment regions (MARs) has been explored extensively in plants for gene expression enhancement in transgenic plants, if not in barley. However, with the genetic transformation of barley, either by microprojectile bombardment or *Agrobacterium*, now being routine in many laboratories, there is a need to shift the focus from single gene transfer and function to multiple transgene transfer and function. The relevance of multiple transgene integration has a direct bearing on complex quality traits, such as starch biosynthesis. The transfer of large inserts carrying genes involved in starch biosynthesis would be valuable for *in planta* studies of starch modification. The possibility for transferring large fragments of DNA to plant genomes via *Agrobacterium* and specialized vectors has been demonstrated. Binary bacterial artificial chromosomes (BIBAC) vectors have been developed for plant transformation (Hamilton *et al.*, 1996; Hamilton, 1997). Transformation-competent artificial chromosome (TAC) vectors (Liu *et al.*, 1999) carrying large-insert genomic DNA of hexaploid wheat have also been developed (Liu *et al.*, 2000). Using these TAC vectors in *Agrobacterium*, transgenic rice carrying an 80kb insert was recovered (Liu *et al.*, 2002). Even though stability of these large inserts is still questionable, progress has been made in elucidating factors causing such instability and efficiency for transformation of tomato (Frery and Hamilton, 2001), potato (Song *et al.*, 2003), and rice (Nakano *et al.*, 2005). The availability of vectors carrying large inserts would enable a multi-gene linking approach to tandemly join a number of the cloned starch biosynthetic genes, for example, and study their effects on changes in starch biosynthesis. Lin *et al.* (2003) used such an approach to stack multiple genes (including 10 genes and functional DNA elements) into a TAC vector and successfully produced transgenic rice plants. Furthermore, gene interactions can be studied by pyramiding only those suspected to be involved in the concerted metabolism of starch.

2.4 Transgene Expression Inheritance

Instability of transgene expression in plants is often associated with complex multicopy patterns of transgene integration at the same locus that

results in inverted repeats and a variety of other position effects due to random integration. Inactivation of transgene expression is often observed in plants and is especially problematic in cereal crops. Using biolistic transformation methods, there are often complex, multicopy transgene integration patterns, where it has been observed that more than 50% of T₁ plants exhibit transgene silencing (Wan and Lemaux, 1994; Pawlowski *et al.*, 1998) and the number of plants with a tendency to silence continues to increase during generation advance (Bregitzer *et al.*, 1998). The majority of cases of transgene silencing are correlated with the presence of multicopy inserts, sequence rearrangements, and random integration into the genome. The insertion of single copies of transgenes increases the probability of transgene expression stability; however, silencing is also observed in plants with single, simple-pattern transgene inserts, even *Agrobacterium*-generated transgenic plants with single copies of the transgene.

Based on the maize transposable elements *Ac* and *Ds* a method was generated that led to large numbers of transgenic barley plants, each carrying a single transgene copy at a different location (Koprek *et al.*, 2000). The plants were developed by crossing barley plants expressing *Ac* transposase (*AcTPase*) with plants containing one or more copies of another transgene expressing a herbicide resistance gene, *bar*, which was contained between inverted repeat *Ds* ends. In the F₂, derived from selfing of F₁ plants, plants were identified in which transposed *Ds-bar* copies had segregated away from the original location that included the selection gene and plasmid backbone and from *AcTPase*.

Of the transposed elements, an estimated 25% had transposed to unlinked locations and 75% to linked sites. Transgene expression from *bar* was 100% stable in F₂ plants, while only 23% of F₂ plants with *Ds-bar* at the original site (introduced by bombardment) expressed stably from the transgene. In F₃ and F₄ populations, transgene expression in 81.5% of plants from plants with single copy transposed *Ds-bar* remained completely stable. Analysis of the integration site in the single copy plants indicated that *Ds-bar* transposed into single or low copy regions of the genome, whereas silenced *Ds-bar* elements at their original location were in redundant or highly

repetitive genomic regions. Methylation of the nontransposed transgene and its promoter, as well as a higher condensation of the chromatin around the original site of integration, was observed in plants exhibiting transgene silencing (Koprek *et al.*, 2001; Meng *et al.*, 2006).

A factor that might play a decisive role in transgene expression stability is the nature of the chromosomal location of the insertion, which varies from line to line. By analyzing the sequences flanking *Ds-bar*, it was determined that most transposed elements reinserted into single copy genomic DNA regions; 87% into genic regions (Singh *et al.*, 2006).

2.5 Tailoring Specialty Products

Barley is mostly recognized for its malting or feed uses. In recent years, there has been an interest to develop barley for other uses. Barley has been incorporated to some extent in wheat bread, soups, porridge, breakfast cereals, stews, baked goods, and production of maltose syrups. Other uses of barley for purposes such as the production of enzymes, oral vaccines, antibodies, pharmaceuticals, and vitamins would be the result of genetic engineering. The large-scale production of xylanase in barley grains (Patel *et al.*, 2000) is a good example of possible industrial application. Uses specifically related to grain composition could be achieved by traditional breeding and selection approaches. The production of high amylose or high amylopectin barley and varying percentages of these two components may be achieved without genetic engineering. The ratio of amylose:amylopectin has been implicated among other factors to play a role in industrial starch films (Koskinen *et al.*, 1996). It has been reported that a high percentage of amylopectin leads to reduction in flexibility, burst resistance, and tensile strengths of films (Wolff *et al.*, 1951) and therefore, barley grains with starch composition suited for this purpose could be developed. The bioplastics properties of starches from potato, corn, wheat, and rice have been studied (van Soest *et al.*, 1996) and similar studies could be initiated for barley starches. The novel uses for barley are still in the early stages of conception. This is due to its high economic value as malt and therefore, more resources are being allocated to that end.

2.6 Intellectual Property and Patent Landscape

Issues relating to intellectual property and patents have become highly debated and publicized in the recent years in plant biotechnology. This is mainly due to the perceived market value of biotechnology-derived products. There are number of patents related to barley for biotechnological purposes. Table 4 shows some of the patents that have relevance to barley transformation. The two main methods for transformation, i.e., microprojectile bombardment and *Agrobacterium* mediated, are covered under their own respective patents. With regards to cereals relevant patents that are likely to be of value in terms of transformation include the one employing vacuum infiltration and *Agrobacterium* (Kloti, 2001) and the other using particle bombardment of germinating barley mature embryos (Wu and Rodriguez, 2000) (Table 4). Furthermore, several of the genes (e.g., *phosphomannose isomerase*, *bar*, *hyg*) used for selection of transformation events are also patented. There is, however, a patented barley green regenerative tissue method (Lemaux and Cho, 2003; Table 4) that is available for nonexclusive licensing. Recently, to bypass patent-related issues governing *Agrobacterium*-mediated transformation, gene transfer to plants by other bacteria besides *Agrobacterium* has been explored (Broothaerts *et al.*, 2005), wherein *Rhizobium* sp., *Sinorhizobium meliloti* and *Mesorhizobium loti* carrying disarmed Ti plasmids were shown to be competent for transformation and are available as open-source-modeled licenses and are not commercialized. Details of this technology are available under the Bioforge project (<http://www.bioforge.net>) and Biological Innovation for Open Society (BIOS) at <http://www.bios.net>.

2.7 Risk Assessment

Regulation of the products of biotechnology is a very dynamic issue. Not only does nearly every developed country have very different approaches to regulations, but many underdeveloped nations also have yet to define how they will regulate these products or how they will deal with import and export issues. For current country details, see USDA Foreign Agricultural Service Global

Table 4 Some barley-specific biotechnology patents

Title	Inventors	Patent #	Date
Construction of barley with reduced gel protein	Hirota, N., Kihara, M. and Ito, K.	USP 7 074 986	July 11, 2006
Transposon tagging and gene delivery in small grain cereals	Lemaux, P.G., McElroy, D. and Koprek, T.	USP 6 951 972	October 04, 2005
Modified barley α -glucosidase	Henson, C.A., Muslin, E.H. and Clark, S.E.	USP 6 849 439	February 01, 2005
Methods and means for producing barley yellow dwarf virus resistant cereal plants	Waterhouse, P. and Wang, M.-B.	USP 6 777 588	August 17, 2004
Barley gene for thioredoxin and NADP-thioredoxin reductase	Cho, M.-J., del Val, G., Caillau, M., Lemaux, P.G. and Buchanan B.B.	USP 6 833 493	December 21, 2004
Method for preparing barley green regenerative tissue	Lemaux, P.G. and Cho, M.-J.	USP 6 541 257	April 01, 2003
Low lipoxxygenase 1 barley	Douma, A.C., Doderer, A., Cameron-Mills, V., Skadhauge, B., Bech, L.M., Schmitt, N., Heistek, J.C. and van Mechelen, J.R.	USP 6 660 915	December 09, 2003
Barley gene for thioredoxin and NADP-thioredoxin reductase	Cho, M.-J., del Val, G., Caillau, M., Lemaux, P.G. and Buchanan B.B.	USP 6 380372	April 30, 2002
Seed-preferred promoter from barley	Jiao, S., Habben, J.E., Niu, X. and Olsen, O.-A.	USP 6 407 315	June 18, 2002
Methods and apparatus for transformation of monocotyledonous plants using <i>Agrobacterium</i> in combination with vacuum filtration	Kloti, A.S.	WO/2001/012828	January 22, 2001
Methods for producing transformed cells of barley	Rikiishi, K., Noda, K. and Kihara, M.	USP 6 291 244	September 18, 2001
Methods for rapidly producing transgenic monocotyledonous plants	Alpeter, F. and Popelka, J.-C.	WO/2001/073084	October 04, 2001
Method for barley transformation	Wu, L. and Rodriguez, R.L.	USP 6 100 447	August 08, 2000
A methods for producing transformed cells of barley	Rikiishi, K., Noda, K. and Kihara, M.	WO/1999/004618	February 04, 1999
Tolerance of trichothecene mycotoxins in plants and animals through the modification of the ribosomal protein l3 gene	Harris, L., Gledlie, S.C. and Simmonds, J.A.	WO/1999/009173	February 25, 1999
Barley β -amylase structural gene	Yoshigi, N. and Okada Y.,	USP 5 726 057	March 10, 1998
Cloned α -glucosidase from barley	Skadsen, R.W. and Tibbot, B.K.	USP 5 763 252	June 09, 1998
Tissue-specific promoter	Okada, Y., Yoshigi, N., Ito, K. and Kihara, M.	WO/1997/002353	January 23, 1997

Agriculture Information Network (GAIN) reports (<http://www.fas.usda.gov/scriptsw/AttacheRep/default.asp>).

When developing regulations, one must first define all the risks associated with the new technology or product of the technology. Assessment of the risks associated with the production of transgenic barley, or for that matter any other transgenic plant event, may involve factors ranging from health and environmental safety to market acceptance to socio-economic issues. Many countries have chosen to regulate on a science-based regime involving

a thorough evaluation of the safety to humans, animals, and the environment. Other countries have given greater weight to socio-economic issues and market acceptance. In this section, we will discuss the scientific risk as it pertains to human, animal, and environmental safety.

2.7.1 Human and animal health

To date, no corroborated ill effects on human health have been attributed to the consumption

of biotechnology-derived foods. There have been numerous studies evaluating the safety of foods derived from genetically engineered crops conducted by several national regulatory authorities using procedures consistent with internationally agreed principles (ICSU, 2003), but they have yet to find any nutritionally deleterious effects as a result of the consumption of commercially available genetically engineered foods. This is not to say that there are no risks, as this cannot be said of foods developed from conventionally bred crops. To truly evaluate long-term human safety, two large, culturally diverse subsets of the population—one eating biotechnology derived foods and one not—would have to be monitored through their entire life span. As this approach is currently unrealistic, food safety risk assessment must attempt to identify probable risks associated with the consumption of these foods by humans and animals. These risks may include the unintended presence of allergens and toxins, the development of antibiotic resistance, and unintentional changes in food composition caused by the genetic engineering process. It is difficult if not impossible to test food safety of whole foods and feeds with animal tests. Despite what nonexperts commonly think, animal tests are not the gold standard. Compositional analysis and toxicity testing of individual components is much more sensitive than whole foods testing (International Life Sciences Institute, 2004). Preventing adverse health effects requires the application of appropriate scientific methods to predict and identify unintended compositional changes that may result from genetic modification of plants, animals, and microbes. However, it is the final product, rather than the modification method or process that is more likely to result in unintended adverse effects (National Academy of Sciences, 2004).

On an international basis, the WHO and FAO through the Codex Alimentarius Commission *ad hoc* Intergovernmental Task Force on Foods Derived from Biotechnologies have developed and continue to develop standards, guidelines, and recommendations for foods derived from biotechnology. However, each member government has the responsibility to formulate and implement its own policies. The regulatory approval process in each of the 21 countries currently growing transgenic crops (James, 2005) is distinct, but

most of them regulate on the basis of process, or in other words conducts risk assessments based on the fact that the product was created by genetic engineering. Table 5 outlines the main countries currently growing transgenic crops and the regulatory agencies overseeing their risk assessment.

Canada is currently the only country that regulates based on the concept of “novelty”. Plants with novel traits (PNTs) are defined “*as any plant containing a trait not present in plants of the same species already existing as stable, cultivated populations in Canada, or is present at a level significantly outside the range of that trait in stable, cultivated populations of that plant species in Canada*” (CFIA Directive 94-08). This essentially means that any new trait, regardless of how it was introduced [e.g., ribosomal DNA (rDNA), mutagenesis, or traditional breeding techniques], may be considered novel. This definition of novelty also translates to animal feed derived from plants if “*the feed is not substantially equivalent in terms of the use and safety of an approved feed ingredient*” (Feeds Section, CFIA).

2.7.2 Environmental concerns

When it comes to protecting the environment, primary concerns are transfer of genes to nontarget species, the potential for invasiveness or weediness, effects of traits on nontarget organisms and, depending on the trait, the potential to create weeds or diseases with resistance to the introduced trait, such as herbicide resistance or disease resistance, respectively.

On an international basis of risk assessment for living modified organisms (LMOs), over 138 countries, including Canada and members of the European Union, have signed the Cartagena Protocol on Biosafety. This document lays out general principles and steps regarding scientific risk assessments for the intentional introduction of LMOs into the environment. The Protocol, while requiring signed parties to adopt measures and strategies to manage and controlling any risks identified, does not develop these policies. They are developed by the individual country and its appropriate regulatory agency (Table 5). Several countries, such as the United States and Australia, have chosen not to sign the

Table 5 Regulatory agencies responsible for food, feed, and environmental safety of transgenic crops^(a)

Select countries growing GM Crops	GM crop area (million hectares)	Main regulatory agency(s) responsible for food/food ingredient/feed safety evaluation	Main regulatory body responsible for environmental safety evaluation
USA	49.8	Food and Drug Administration (FDA)/United States Department of Agriculture (USDA)	Environmental Protection Agency (EPA)
Argentina	17.1	National Agrifood Health and Quality Service (SENASA)	National Advisory Commission on Agricultural Biotechnology (CONABIA)
Brazil	9.4	National Bio-safety Council Technical Commission (CTNBio)	
Canada	5.8	Health Canada/ CFIA (Canadian Food Inspection Agency, 2008)	CFIA, Plant Biosafety Office (PBO)
China	3.3	Ministry of Agriculture (MOA)—Biosafety Administration Office

protocol but have policies in place to assess environmental risks and appropriate management practices.

As with traditional agriculture, associated risk can often be managed with good agricultural practices. The same can be said for potential risks associated with transgenic crops. Good farming and manufacturing practices for transgenic crops deemed to be safe for release into the environment must follow a strict regime to minimize the possibility of any of the identified risks. These practices may include the implementation of buffer crops, isolation distances, and proper crop rotation schedules.

Barley, in relation to gene flow, has been described as a low risk crop (Eastham and Sweet, 2002; Ritala *et al.*, 2002) due to its self-fertilizing nature, the small amounts of pollen produced and the low frequency of outcrossing. With the use

of adequate isolation distances and other best management practices, these risks can be managed but cannot achieve zero risk.

Volunteers from small grain, such as wheat and barley, can be issue. Typically management techniques such as proper rotations, preseed weed burn-off, and herbicide applications are used to control these issues. With a herbicide tolerant (HT) barley variety, management using chemicals can become a bit more difficult, but a variety of chemicals are available for use, making even the situation with HT transgenic barley crops manageable.

2.8 Public Acceptance and Awareness

Since the dawn of technological advances, public perception of newer technologies has generally

not been forthright. This dread for novelty is often due to a lack of information/education. This fear of technology could not be more apparent than by observing the “GMO (genetically modified organisms) polemic.” With regards to the important grain commodities, public awareness and consumer acceptance of biotechnology for grain value enhancement are likely to be key components for the success of further biotechnological developments. However, GM grains, although likely proven to be of potential value, are going to be a success story only as a result of improved consumer acceptance (Jones and Jones, 2004). It is therefore imperative that the benefits and risks of GM grain products be extensively discussed to allow consumers to make well-informed choices.

2.8.1 Measuring acceptance and awareness

In the past decade, numerous studies have been conducted to try to judge public perception, but interpreting results has not been an easy task.

For example, a recent survey (Eurobarometer 64.3, 2005) asked Europeans questions to gauge their opinion on GM foods. The result of this survey stated that 58% oppose the technology while 42% support it. A different study of Europeans was based on the concept of food safety (European Food Safety Authority, 2005). When they asked the public, “*What are all the things that come to mind when thinking about possible problems or risks associated with food?*” only 8% responded—GMOs.

Public acceptance and awareness of foods derived from biotechnology are generally low. These levels appear to have either stayed the same or only slightly improved over the last several years, according to a number of public surveys, as seen in Table 6. A positive association between acceptance and education has been identified (Hallman *et al.*, 2003), although the largest sector of the public remains undecided. Several studies have shown that support for these technologies typically increases after an explanation of the risk and benefits are discussed (McCormick, 2003; IFIC Food Biotechnology Report, 2006).

Table 6 Results of several recent opinion polls on public support for biotechnology^(a)

Organization	Country	Number of participants	Results
Awareness Biotechnology Australia (McCormick, 2003)	Australia	500	23% support GM foods 42% support GM after benefits and risks addressed
Pew (Pew Initiative on Food and Biotechnology, 2006)	United States	1000	Opposition declined from 58% to 46% since 2001—support has been stable at 27% in 2006
Eurobarometer (2006)	Europe	25 000	Over 50% of Europeans believe biotechnology will improve their quality of life—particularly for medicine and bio-based industrial applications 27% support GM foods
IFIC (2006)	United States	1000	72% of consumers say they are confident in the safety of the US food supply 32% of consumers have a positive view of biotechnology
Food Policy Institute (2003)	United States	1200	49% approve of plant-based GM foods (down from 58% in 2001)
Norfolk Genetic Information Network (2008)	United Kingdom, Denmark, Poland, Mexico, Brazil, Taiwan, Turkey, and United States		58% will not eat GM food 55% support GM food for developing countries 66% support GM crops for cheaper medicines
Genome Canada (Genome Canada Newsletter, 2003)	Canada	1500	56% find biotechnology useful

^(a) Reproduced from Pew Initiative on Food and Biotechnology (2006), McCormick (2003), Eurobarometer (2006), and Genome Canada Newsletter (2003)

It is important to note that surveys are intended only to give a representative view of the general audience. Caution must be exercised when analyzing any survey, as results can be swayed by the manner in which the questions are written or sampling of a nonrepresentative audience. In the end, the final results of consumer acceptance will only be seen when the consumers make their choice at the grocery store.

2.8.2 Information dissemination

The need to increase the general public's awareness of biotechnology is obvious, but the issue is to make the information available in a manner that is open, honest, and unbiased. According to the Special Eurobarometer 238 (European Food Safety Authority, 2005), people find consumer groups, physicians, and scientists as the most reliable sources of information, followed by public authorities. In the recent Pew Initiative Report, friends and family, farmers, and scientists were considered the most reliable sources of information, while trust in the government in the United States substantially dropped to fourth place from first place in 2001. Media in both reports were viewed as the least credible source of information, yet was the most widely reaching. Information, therefore, must come from a variety of sources and deliver messages the general public will find interesting and understandable.

Various organizations around the world are working to educate the public and bring an informed debate. At the primary and secondary school level, a number of innovative websites and programs are running with a goal of educating our youth. In the United States, a series of buses travel across the country which are in essence mobile instructional laboratories. Initially started by the Georgia State University, this concept has been copied across the globe with similar operations occurring in Australia, Canada, and Malaysia. "Celebrate ImaGENEnation" is the theme for Canada's National Biotech Week. A first of its kind, this week long series of events, debates, and lectures is aimed at informing politicians and the public on the innovative research happening across Canada. A number of US university-based educational websites also provide science-based information to end users and the public, for example, <http://www.nbiap.vt.edu>,

<http://www.ucbiotech.org>, <http://www.cls.casa.colostate.edu/TransgenicCrops/hotlabel.html>.

In the past, the benefits of biotechnology-derived crops have been mostly directed at producers. As new technologies are being developed which promise to bring greater direct benefits to the consumer, and increased efforts are aimed at public education, hopefully the public will become more engaged and better informed, allowing them to make more informed decisions.

3. CHALLENGES FOR BARLEY GENETIC MODIFICATION

Barley was generally considered to be recalcitrant to both *in vitro* culture and genetic transformation compared to other cereals like rice. Over the last decade, there have been a number of reports on the successful transformation of barley, including those with traits of value. With the possibility of using *Agrobacterium* for barley transformation, there is likely to be more reports of genetically engineered barley, but particle bombardment will continue to remain a method of choice due to better success to date. It is generally believed that *Agrobacterium* will allow for a more organized integration of the transgenes at low copy numbers with higher stable expression levels, although *Ds*-mediated gene delivery from bombardment events offers an alternative for generating single copy events. However, with *Agrobacterium* there may be DNA rearrangements, deletions, multiple copies, and insertion sites (for review, see Stam *et al.*, 1997). Integration of transgenes in multiple copies or at multiple sites leads to silencing as a result of hypermethylation. In barley, the stability of foreign DNA and the importance of methylation have been recognized and it was suggested that a certain methylation pattern might be necessary for stability of foreign DNA (Rogers and Rogers, 1992). Several subsequent studies have addressed transgene stability, silencing, and methylation in barley (e.g., Koprek *et al.*, 2001; Meng *et al.*, 2003, 2006; Singh *et al.*, 2006). Results suggest that the transposon-mediated DNA delivery system in barley (Singh *et al.*, 2005) will be useful for more successful transgenic events. However, in many other instances due to silencing occurring as a result of multiple copies, it has been suggested that only transgenic lines carrying a single copy of the gene of interest be selected

and advanced (Finnegan and McElroy, 1994; Demeke *et al.*, 1999). Furthermore, the presence of multiple and rearranged copies complicates regulatory approval. Endogenous genes can also be suppressed by transgenes and by using different promoters with the transgenes of interest this can be prevented (Båga *et al.*, 1999). Sequences derived from MARs used to flank transgenes have also been shown to influence stable integration and expression, possibly preventing the transgenes from being affected by surrounding chromatin (Liu and Tabe, 1998). Due to the presence of about 76% repeats in barley (Flavell *et al.*, 1974), use of the MARs flanking strategy should lead to efficient targeting of transgenes to the euchromatic regions thereby enhancing stable expression.

As mentioned earlier, *Agrobacterium*-mediated transformation could also be used to deliver more specialized vectors carrying large inserts such as bacterial artificial chromosomes (see Section 2.3.2). This approach will be particularly useful for transfer of large fragments of DNA with several genes. There are numerous reports indicating the existence of clusters of genes on specific chromosomal segments for specific traits. For example, the existence of gene clusters conferring disease resistance has been reported (Pryor, 1987; Crute and Pink, 1996; Micheltore and Myers, 1998). Clusters such as these have been identified in barley (Jørgensen, 1994; Seah *et al.*, 1998) and the potential for using a BIBAC system for transformation of barley does exist. Furthermore, with the availability of genomics data and quantitative trait loci (QTL) localization for quality traits in barley, transformation using large inserts will be of interest especially for an understanding of biosynthetic pathways such as those of starch. Research efforts also need to continue to address quality attributes in barley to diversify barley uses for food and industrial applications.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Reports on the time and place of oat domestication remain conflicting even though the processes leading to the domestication of oat are tightly linked to the history of the domestication and cultivation of wheat (*Triticum*) and barley (*Hordeum*) species, which were the primary domesticated cereals of Neolithic era agriculturalists in the Near East (Vavlov, 1926; Murphy and Hoffman, 1992). Weedy grasses, such as oat and rye (*Secale cereale* L.), were eventually developed into secondary crops thanks to the selection pressure that were accidentally imposed on admixtures of these weedy plants (Murphy and Hoffman, 1992). Conclusions about the center of origin and evolutionary history for oat are not easy to reach for several reasons. For example, many environmental and chromosomal changes may have taken place over time as well as evolutionary developments, such as modes of seed dispersal or reproductive isolation barriers (Rajhathy and Thomas, 1974; Wesenberg *et al.*, 1992). In addition, these authors indicated that what was once a natural habitat has been changed in recent times via cultivation and seed transport by humans. All or most of the oat species currently overlap in the western-most fringe of the native range (southern Spain, northern Morocco, and northern Algeria), suggesting that the center of origin for *Avena* spp. is probably located in those

areas. Oat was first used as a forage crop in southern Europe long before it was grown for grain (Coffman, 1977). It was first introduced in southern United States in the early to mid 16th century by the Spanish (Coffman, 1977). Oat is adapted to a wide range of soil types with a variety of chemical and physical properties, but it is best adapted to cool and moist climate (Sorrells and Simmons, 1992). Oat production is mostly concentrated between latitudes 35–65°N and 20–46°S. It is principally cultivated in Europe (Sweden, Finland, Russia, Poland, and Germany), the northeastern United States (North Dakota, Minnesota, Wisconsin, South Dakota, and Iowa), Canada, and Australia.

1.2 Taxonomy, Habit, and Cytological Features

The genus *Avena* consists of about 70 different species, but only a few are cultivated. Cultivated oat species consist of *Avena byzantina* C. Koch (red oat) and *Avena sativa* L. (white oat), with the latter being the primary cultivated species. Both these species are hexaploid. The ploidy levels of oats include diploid ($2n = 2x = 14$), tetraploid ($2n = 4x = 28$), and hexaploid ($2n = 6x = 42$) (Rajhathy and Thomas, 1974; Baum and Fedak, 1985; Legget and Thomas, 1995; Li *et al.*, 2000) (Table 1). Four *Avena* genomes, A, B, C, and D, have been identified, and *A. sativa* is a self-pollinated and natural

allohexaploid containing A, C, and D genomes. In oat, three distinct types of juvenile growth are generally recognized, including prostrate, semiprostrate, and erect or upright (Etheridge, 1916; Stanton, 1955). The prostrate growth type develops more tillers and is winter resistant while the most upright early growth is associated with spring (Coffman, 1977). Strength of the culms or standing ability of the plant depends on the number and attachment of the roots as well as the structure of the culms (Hamilton, 1951). Coffman (1977) described two types of roots in oat, seminal and adventitious. The seminal roots originate during embryo development and consist of a jointed primary root (radical) and branches arising at the first node or joint. As for the adventitious roots, they arise at the nodes of the stem and tillers, just beneath the soil surface (Coffman, 1977).

1.3 Economic Importance

For the last 30–40 years, world oat production has markedly declined because of increased mechanization in farming (oats were the principal feed of work horses), competition with other crops (barley, sorghum, and maize) as animal feeds, and low yield gains. Oat yields have been stagnant in part because there is very little genetic diversity in oat germplasm (De Koeper *et al.*, 1999; Langer *et al.*, 1978). Decline in oat production has been particularly pronounced in countries such as the United States (Figure 1) where oat production has decreased about 80% in the last past 30 years. Oat is currently grown on about 13 million hectares, and for the period 2000–2006, the world production has stabilized at around 25 million metric tons. Oat is a multipurpose crop,

Figure 1 Farm mechanization and stiff competition from crops such as soybeans have led to a steady decline in oat production over the years, particularly in the United States [Source: USD-NA]

which is an important source of food for both humans and domesticated animals. It contains many compounds that exhibit antioxidant activity, including vitamin E, phytic acid, phenolic compounds, and avenanthramides (Peterson, 2001). In addition, oat contains the soluble fiber β -glucan, which is reported to be associated with specific health benefits, including lowering blood lipids, regulating blood glucose, protecting against tumor development in the colon, reducing risks of coronary disease. Industrially, oats are used in the production of plastics, pesticides, preservatives, cosmetics, synthetic rubber solvents, disinfectants, and papers as well as in the brewing industries.

1.4 Traditional Breeding Objectives of Oats

Most of the improvement in oat has been achieved using classical breeding methods, which rely mostly on hybridization followed by selection.

In many oat breeding programs, the focus was on improving agronomic characteristics such as yield improvement, suitable maturity, lodging resistance, disease resistance, and environmental stress tolerance. In the United States, disease resistance is the most critical aspect of oat germplasm enhancement and cultivar development, with particular emphasis on crown rust resistance, barley yellow dwarf virus resistance or tolerance, stem rust resistance, and smut resistance (Wesenberg, 2000). Lately, however, more focus has been put on developing oat varieties with improved grain quality, such as high milling yield and increased β -glucan content (Cervantes-Martinez *et al.*, 2001; McMullen *et al.*, 2005).

The most critical issue relative to oat improvement is the marked decline in oat acreage over time, especially in the United States, and the gradual decline in oat research effort in both the public and private sector in North America (Wesenberg, 2000).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Oat Breeding

Traditional breeding has been successfully used to develop hundreds of improved oat cultivars; however, the process is time consuming. Also, hybridization barriers could hamper the process. Therefore, attempts have been made to incorporate molecular breeding tools, such as genetic transformation to introduce certain genes of interest into the oat genome. In addition to speeding up the development of improved cultivars, genetic engineering can be very useful in a crop such as oat, which has a huge genome. Genetic engineering can be used to add new traits or improve existing traits in oat by introducing genes from any other organisms into oat or by manipulating oat genes for increased expression (Somers, 1998). Some of the goals of oat genetic engineering include identification of gene promoter sequences for high levels of tissue-specific transgene expression, virus and fungus disease resistance, modification of grain composition and agronomic traits using genes from other organisms and antisense suppression of endogenous homoeologous genes, and tolerance to abiotic stress (Koev *et al.*, 1998; Somers, 1998; Torbert *et al.*, 1998a; Kelley, 2001; Maqbool *et al.*, 2002; Oraby *et al.*, 2005). However, in order to reach these goals, two prerequisites must be met, namely a dependable regeneration system and an efficient transformation method.

2. DEVELOPMENT OF TRANSGENIC OATS

2.1 Tissue Culture in Oats

2.1.1 Callus- and meristem-based regeneration systems

Production of plants from transformed callus using regenerable oat genotypes (Table 2) in a callus-based regeneration system is one of the schemes applied in oat transformation. Monocots are generally recalcitrant in tissue culture and typically exhibit genotype-specific regenerability (Chowdhry *et al.*, 1993). *In vitro* plant regeneration from a callus-based system offers a great potential for production of larger numbers of plants.

However, with the exception of the derived genotype, Gaf/Park, and its derived selection, GP-1, most oat genotypes, in particular the elite cultivars, are recalcitrant to regeneration through somatic embryogenesis. Callus-based regeneration protocols have been developed for oats (Cummings *et al.*, 1976; Heyser and Nabors, 1982; Bregitzer *et al.*, 1991; Gana *et al.*, 1995; Hassan *et al.*, 1999; Kelley *et al.*, 2002a, b), but the apparent inability to de-differentiate reflects a fundamental property of oats, rather than simply a negative response to the traumatic and artificial conditions of tissue culture (Christou, 1995). Callus cultures of most oat cultivars either result in a low frequency of plant regeneration or fail to produce plants at all. In addition, with time, progressive callus subcultures result in loss of plant regenerability due to reduced somatic embryogenesis and other developmental barriers. Somaclonal variation also occurs often because of the length of time required by the callus culture process. Cellular and morphogenic events during somatic embryogenesis of oats appear to be controlled by an array of conditions, including medium composition, physical environment, and genetic effects (Altman *et al.*, 1990).

Despite the problems mentioned above, some progress has been achieved in oat callus-based regeneration during the last few decades (Table 2). For example, Torbert *et al.* (1998b) surveyed 16 elite oat genotypes to determine if they are capable of producing somatic embryos from mature embryos. Fifteen out of the 16 lines tested produced embryogenic callus, and only the line Milton failed to produce any callus at all. This group also succeeded in transforming the cultivar Belle via particle bombardment of mature embryo-derived embryogenic callus. In addition, cultivar Tibor (*A. nuda*) (low plant regeneration), experimental line GP-1 (*A. sativa*) (high plant regeneration), and their crosses, GP-1 x Tibor and Tibor x GP-1, were grown on putrescine-containing media to determine the effects of putrescine on somatic embryogenesis and plant regeneration (Kelley *et al.*, 2002b). Analysis of the effect of putrescine on each genotype revealed that the addition of 0.5 mM putrescine to a shoot proliferation medium enhanced the formation of somatic embryos and thus subsequent plant regeneration. Regeneration of plants from Tibor opens the possibility for the transformation of this agronomically important cultivar, and these

results suggest that putrescine may be used to induce or enhance somatic embryogenesis in more agronomically important oat cultivars.

Meristem-based regeneration systems are genotype independent and have the potential for producing a high number of fertile plants in a tissue culture environment (Kelley *et al.*, 2004). Because the culture time is shorter than that for the callus-based regeneration, meristem-based regenerated plants may be less prone to somaclonal variation.

2.1.2 Sources of explants

Several sources of explants, including leaf bases, anthers, vegetative shoots, roots, mesocotyls, hypocotyls, and protoplasts, have been used in oat tissue culture, but immature and mature embryos have been the most commonly used explant sources for establishment of regenerable tissue cultures of oat, and somatic embryogenesis is the most widely used regeneration pathway (Table 2). However, immature embryos do not lend themselves well to particle bombardment because callus initiation arises from the mesocotyl of the immature embryo, a very small target for biolistic transformation (Torbert *et al.*, 1998a). Regeneration and transformation systems based on shoot meristematic cultures have been developed (Zhang *et al.*, 1999; Maqbool *et al.*, 2002; Cho *et al.*, 2003; Kelley *et al.*, 2004). Compared to callus-based cultures, shoot meristematic cultures have several advantages, including generation of more vigorous plants and the potential for increased genetic stability (Zhang *et al.*, 1999). In addition, shoot meristematic cultures are genotype independent; therefore, the method can be extended to elite oat cultivars, which are generally recalcitrant to callus-based regeneration system.

2.2 Transformation of Oats

Plant transformation is predicated upon the availability of an efficient gene delivery method and a routine and reliable regeneration system. *Agrobacterium*-mediated transformation, particle bombardment, and protoplast transformation are the most widely used gene delivery methods. Most of the original experiments and breakthroughs in genetic transformation have been performed

with species belonging to the Dicotyledonae. The Poaceae genera, particularly *Avena*, have not been used in genetic engineering efforts commensurate with their economic importance nor to the extent that they are consumed as a caloric or protein source. One of the reasons for this is that the preferred plant transformation system has been *Agrobacterium*-mediated and until recently, monocots, traditionally, had not responded to the proper, efficient transfer of the transfer DNA (T-DNA) (Christou, 1995). More successful for monocot transformation has been biolistics (Hagio *et al.*, 1991), which employs high velocity metal particles to deliver biologically active DNA into plant cells (Christou, 1995).

2.2.1 Gene delivery methods

2.2.1.1 Particle bombardment-mediated transformation

Until recently, the method of predilection for transferring genes into monocot plant genomes was biolistics (biological ballistics), also referred to as “gene gun” or particle bombardment. The biolistic technique, first developed by Sanford *et al.* (1987), consists of introducing genetic material into intact cells and tissues through the use of high-velocity microprojectiles. DNA containing genes is coated onto microcarriers (tungsten or gold particles) and loaded onto macrocarriers, which are accelerated under slight vacuum into barriers, whereby the microcarriers are then accelerated into target tissues or cells. Particle bombardment is genotype independent, and it has virtually no inherent host range limitations and is not restricted to certain specific tissues or cells. Successful transformation of hexaploid oats was first achieved using the particle method to genetically transform friable embryogenic callus cultures (Somers *et al.*, 1992). Since then, the same approach has been employed to transform other oat explants, such as meristematic cultures (Zhang *et al.*, 1999). However, the percentage of cells that are stably transformed by this method remains low as compared to *Agrobacterium*- or protoplast-mediated transformation. In addition, the method is prone to high copy number insertion, which may lead to transgene inactivation. Particle bombardment was also reported to produce more transgene rearrangements (Songstad *et al.*,

1995; Pawlowski and Somers, 1998), but this assertion has been challenged by a recent study (Kohli *et al.*, 1999). Even the superiority of *Agrobacterium*-based DNA delivery techniques over direct delivery methods has been called into question (Repellin *et al.*, 2001).

2.2.1.2 *Agrobacterium*-mediated transformation

For the dicotyledonous species, *Agrobacterium*-mediated gene delivery system remains the method of choice because it is more reliable and efficient, and transformation efficiencies can be in the range of 70–80% (Wilkins *et al.*, 2000). The *Agrobacterium* gene transfer technique is based on the natural ability of the soil-dwelling *Agrobacterium tumefaciens*, containing a tumor-inducing Ti plasmid, to introduce a portion of its DNA into a plant cell as a part of its normal pathogenic process (Matzk *et al.*, 1996). It has been successfully used to transform many plant dicotyledonous species. However, monocotyledonous species traditionally had not responded well for the efficient transfer of the T-DNA (Christou, 1995) because they were thought to be out of the range of *Agrobacterium* transformation (Potrykus, 1990), although in nature, some monocotyledonous species are susceptible to *Agrobacterium* infection (De Cleene and De Ley, 1976). The first reports of transformed dicotyledonous plants via *Agrobacterium*-based technique appeared in the early 1980s. Since then, transgenic monocotyledonous species have also been produced using this method, including transgenic rice (Chan *et al.*, 1992; Hiei *et al.*, 1994; Dong *et al.*, 1996), wheat (Cheng *et al.*, 1997), barley (Tingay *et al.*, 1997; Fang *et al.*, 2002), rye (Popelka and Altpeter, 2003), and *Alstroemeria* (Akutsu *et al.*, 2003). The *Agrobacterium*-mediated transformation method appears to be best suited for lines that undergo somatic embryogenic regeneration, so its use would be mostly limited to a few oat genotypes because many elite oat genotypes remain recalcitrant to somatic embryogenesis. However, transformed rice plants have been obtained from isolated shoot apices following *Agrobacterium* inoculation (Park *et al.*, 1996). *Agrobacterium*-mediated transformation of monocots appears to be influenced by several

factors, including genotype, explant type, pretreatment, inoculation, and co-culture conditions, *Agrobacterium* strain, plasmid, and selectable marker (Cheng *et al.*, 2004). Currently, particle bombardment appears to be the method of choice for oat transformation, and several oat genotypes have been genetically engineered using this method. There seems to be no published reports of successful *Agrobacterium*-mediated transformation for oat (Table 3).

2.2.1.3 *Protoplast*-mediated transformation

Protoplast-mediated transformation was among the first methods of direct gene transfer in plants, particularly in cereals such as rice (Toriyama *et al.*, 1988; Zhang *et al.*, 1988) and maize (Golovkin *et al.*, 1993). Direct gene transfer to protoplasts is appealing because no biological vector is needed, and it has the potential to pave the way for oat somatic hybridization. Somatic hybridization can be particularly useful for the transfer of desirable traits that are controlled by polygenes or uncloned genes and for the generation of novel gene combinations by overcoming sexual crossing barriers (Binsfeld *et al.*, 2000). However, the isolation and culture of protoplasts is a difficult and time-consuming procedure. The lack of a dependable and routine regenerable protoplast system constitutes a major limitation to the greater use of *in vitro* genetic manipulations in oat (Rines *et al.*, 1992).

2.3 Reporter and Selectable Marker Genes Used in Oat Transformation

There are several reporter genes, including the *GUS* and *GFP* genes, used in plant biotechnology to monitor gene transfer and expression and help in the recovery of transformed plant cells, tissues, or organs. The *UidA* gene for β -glucuronidase (*GUS*) of *Escherichia coli* has been one of the most widely used genetic markers in the study of foreign gene expression in plants (Willmitzer, 1988; Walden and Schell, 1990). The *GUS* assay has several advantages. The procedure is fast, nonradioactive, and sensitive, and it allows for both quantitative (level of expression) and qualitative (specificity of expression in tissues and

Table 3 Several oat genotypes have been genetically modified using particle bombardment method

organs) information. In rare cases, the *GUS* gene has been used as a selectable marker (Jefferson, 1989). There was the general assumption that there was no detectable intrinsic *GUS* activity in higher plants, but studies have found that *GUS*-like activity was widely distributed in seed plants (Hu *et al.*, 1990). The *GUS* gene has been by far the most extensively utilized reporter gene in oat transformation (Table 4). However, there are several drawbacks associated with the *GUS* assay, including endogenous activity, background signal from microbial contaminants, instability of some fluorescent stain products, and toxicity to plant cells (Hodal *et al.*, 1992; Guivarc'h *et al.*, 1996; Kaeppler *et al.*, 2001). Because of these limitations, new reporter genes, such as the *GFP* reporter gene, have been developed to increase the efficiency and flexibility of cereal transformation (Kaeppler *et al.*, 2001). *GFP* does not interfere with cell growth and function; therefore, it can be used in both nonlethal selection and in co-transformation schemes where it is detected by irradiation with near ultraviolet (UV) light or blue light. Thus the damage caused by lethal selection of transformants using antibiotics or the sacrifice of valuable transformed tissue for *GUS* assay can be avoided.

Transformation systems require a selection system in an attempt to generate nonchimeric transgenic plants. Antibiotics and herbicides have served as the most popular selectable markers to generate genetically modified plants. Selectable marker genes encode proteins rendering the transformed cells resistant to an antibiotic or herbicide that is used for selection. Therefore, a medium containing a selectable toxin allows for the survival of the transformed cells, while the nontransformed cells are killed or lag in growth. The *bar* gene, isolated from *Streptomyces hygroscopicus* (Thompson *et al.*, 1987), has been widely used, particularly in grasses and legumes. The recovery of transformed cells of cereals is generally achieved by using a positive selection system for cells that are resistant to herbicides or antibiotics. However, transformation of herbicide resistance is of great concern in oats because oat relatives are common weeds and readily cross with the cultivated *Avena*, possibly resulting in ecological and agricultural problems. Antibiotic selection was also of concern, but the common presence of already resistant bacteria lessens the risk of ecological disturbance. Therefore, antibiotics have

been the selection system of choice for oats and many other crop plants (Torbert *et al.*, 1995).

2.4 Value-Added Traits

Ongoing efforts to incorporate molecular breeding tools into breeding programs to improve oat germplasm include transgenics, molecular markers, and genomics. Plant transformation technology has made it possible to insert foreign genes of interest into plant genomes with more precision in overcoming sexual incompatibility as well as species barriers between organisms. Most of the genetic engineering in oat has involved the introduction of reporter and selectable marker genes into the oat genome of the modified oat genotypes (Tables 3 and 4). However, a few oat cultivars have been modified by introducing potentially value-added traits, such as the barley yellow dwarf virus (BYDV) resistance gene (Koev *et al.*, 1998) and the barley *hva1* gene for tolerance to osmotic stresses (Maqbool *et al.*, 2002; Oraby *et al.*, 2005).

BYDVs are the most serious and ubiquitous economically important viruses of several small grains, including wheat, barley, and oats. Koev *et al.* (1998) transformed oat plants with the 5' half of the BYDV strain PAV genome, which includes the RNA-dependent RNA polymerase gene by bombarding callus cultures of GAF/Park, a nonagronomic but highly regenerable oat line. Two gene constructs, p35S39K60K and p35S99K, which were used are described as follows (Koev *et al.*, 1998). The construct p35S39K60K consisted of the 5' untranslated region (UTR) of BYDV-PAV and wild type ORFs 1 and 2 preceded by the cauliflower mosaic virus double 35S promoter and followed by the nopaline synthase (*nos*) transcription termination signal. The construct p35S39K60K was developed in two steps: (1) The p35SPAV5' (bases 1–1596) construct was generated by polymerase chain reaction (PCR) using pPAV6 full-length BYDV-PAV plasmid as a template. The upstream primer (5'-ACGGGATCCGAGTGAAGATTGACCATCTTCACA-3') contained a *Bam*HI site and the first 23 nucleotides of the 5' end of the BYDV-PAV genomic RNA, and the downstream primer (5'-ATGAAGCTTGACATTGGCATCCTTCTGATG-3') was complementary to viral bases

Table 4 Commonly used reporter genes and selectable markers in oat transformation

1596–1569 including a *Hind*III site. The *Bam*HI-*Hind*III-cut PCR fragment was gel purified and cloned into pAGUS1, which had been cut with the same enzymes, resulting in plasmid p35SPAV5'. (2) The *Hind*III-*Bst*1107I (bases 1591–2787) fragment from pPAV6 was cloned into *Hind*III-*Eco*RI-cut p35SPAV5', resulting in p35S39K60K. As for the second gene construct, p35S99K, a stop codon of ORF 1 UAG, was mutated to UCAG, which brought ORFs 1 and 2 into the same ORF. If translated, this construct would produce only the 99-kDa protein and not the 39-kDa protein. This construct was generated by cloning the *Bgl*II-*Sac*I (bases 856–2453) fragment from pFLFSM4 into p35S39K60K, which had been cut with the same enzymes. The resulting genetically transformed T₂- and T₃- plants showed tolerance to BYDVs.

Water deficiency is a major environmental stress factor limiting crop production. Salt affected soils contribute to accentuating this abiotic stress by reducing the amount of usable water by the plants, thus reducing crop production in many parts of the world. Developing crop plants capable of withstanding abiotic stresses would help reduce water use (FAO, 1999). Maqbool *et al.* (2002) genetically engineered three oat (*A. sativa* L.) cultivars, “Ogle”, “Pacer”, and “Prairie”, by biolistic bombardment of multiple shoots derived from oat apices. Two plasmids were used: BY520 and Act1-D. The plasmid BY520 contained a selectable marker/herbicide resistant *Streptomyces hygroscopicus bar* (Phosphinothricin

acetyl transferase) gene and the barley *hva1* gene. The selectable marker *bar* is driven by CaMV 35S (cauliflower mosaic virus promoter) and the *nos* (*Agrobacterium* nopaline synthase gene) 3' noncoding region, while *hva1* is driven by *Act1* (5 region of the rice actin 1 gene) and terminated with the *pinII* (potato protease inhibitor II gene) 3 noncoding region. The plasmid Act1-D contained the *E. coli* β -glucuronidase (*gus*) gene flanked by the *Act1* promoter and the *nos* terminator. The resulting T₂- and T₃- generation plants showed very high levels of tolerance to osmotic stress (salt and mannitol) under *in vitro* conditions. Later, Oraby *et al.* (2005) investigated the third generation of the same transgenic oat (cv. Ogle) plants under greenhouse conditions and reported significant increase in tolerance to salt stress (200 mM NaCl) for traits such as number of days to heading, plant height, flag leaf area, root length, panicle length, number of spikelets/panicle, number of tillers/plant, number of kernels/panicle, 1000-kernel weight, and kernel yield/plant.

2.5 Challenges Facing Oat Transformation

Some of the challenges facing oat transformation are related to environmental and health concerns. The usefulness of antibiotics and herbicides as selectable markers has been demonstrated, but questions and concerns have been raised about the potential risks associated with their use in

transformation schemes. One concern often voiced is whether antibiotic resistance genes could be inadvertently transferred horizontally from plant cells to bacteria living in nature or in the guts of animals and humans. This would render the bacteria resistant to antibiotics, making these useless for treating bacterial diseases. As for the herbicide selectable markers, one of the main concerns is that the transgenic plant may cross with a weedy relative, thus making that weed resistant to herbicide. This is for example the case for oat. Also, the potential for the presence of herbicide residues in food products is a source of concern. Furthermore, even though the current scientific evidence indicates that there is no significant risk in consuming genetically modified food (Bouchie *et al.*, 2002), there remain concerns among the general public. The main concerns voiced include inadvertent introduction of toxins and allergens, change in the levels of essential nutrients, and the compromising of antibiotic therapies (Bouchie *et al.*, 2002). These concerns are sometimes violently expressed by some extremist organizations, such as the Earth Liberation Front, which destroyed 800 transgenic oat plants at the University of Minnesota in 2000. To alleviate some of these concerns, oat transformation systems based on visual selection using GFP as a selectable marker have been developed (Kaeppler *et al.*, 2000, 2001). In addition to environmental and health risk concerns, the dramatic decline in oat production, in particular in leading research countries such as the United States, constitutes a major challenge to oat biotechnology.

3. CONCLUSIONS AND FUTURE PROSPECTS

Recent advances in oat biotechnology have made it possible for breeders to investigate incorporation of molecular breeding tools in breeding programs. Ongoing efforts to incorporate molecular breeding tools into breeding programs to improve oat germplasm include transgenics, molecular markers, and genomics. Plant transformation technology has made it possible to insert foreign genes of interest into plant genomes with more precision in overcoming sexual incompatibility as

well as species barriers between organisms. Most of the genetic engineering in oat has involved the introduction of reporter and selectable marker genes into the oat genome of the modified oat genotypes. However, a few oat cultivars have been improved through the introduction of potentially agronomically useful traits, such as the *hva1* gene for tolerance to osmotic stresses and the BYDV resistance gene.

The major obstacle to oat transformation has been the recalcitrance of most oat genotypes, in particular the elite cultivars, to regeneration through somatic embryogenesis. However, modifications of the culture media have enabled somatic embryogenic regeneration of more oat genotypes, and several oat genotypes have been genetically engineered by particle bombardment (Table 3) using various explant sources, such as leaf bases, mature embryos, and shoot meristems, which have the potential to reduce genotypic effects on tissue culture response (Torbert *et al.*, 1998b). Stable *Agrobacterium* transformation has been achieved in several monocotyledonous crops, including rice, wheat, barley, and *Alstroemeria*. No published reports could be found on the susceptibility of the various oat tissue culture explants to *Agrobacterium* transformation. *Agrobacterium*-mediated gene transfer is reported to have several advantages over biolistics, including higher frequency of gene transfer (Smith and Hood, 1995; Park *et al.*, 1996) and insertion of a well-defined DNA fragment into host genome (Repellin *et al.*, 2001). For the last several decades, substantial progress has been made in oat tissue culture, with the regeneration of several genotypes using various explant types, including shoot meristems (Torbert *et al.*, 1998b; Kelley *et al.*, 2004). Regeneration via meristem is genotype independent, and genetically engineered rice plants have been obtained from shoot apices following *Agrobacterium*-mediated transformation (Park *et al.*, 1996). This technique could be extended to oat to allow for the transformation of more elite oat cultivars. Oat is a source of many compounds with antioxidant activity (Peterson, 2001); therefore, increasing the antioxidant activity of these compounds could be achieved using the improved transformation techniques. In addition, the development of oat transformation systems based on visual selection using GFP as a selectable marker can help alleviate some of the health and environmental

concerns associated with the use of antibiotics and herbicides as selectable markers.

Genetic markers consist of specific locations on a chromosome and serve as landmarks that are used for genome analysis (Staub and Serquen, 1996; Kumar, 1999). There are two basic genetic markers, morphological markers and molecular markers. Morphological markers can be monitored visually and are controlled by a single locus, but their expression can depend on environmental conditions and epistatic pleiotropic interactions (Kumar, 1999). Biochemical markers and DNA markers are molecular markers indicating polymorphisms at the protein and DNA level, respectively. DNA markers include hybridization-based markers, such as restriction fragment length polymorphisms (RFLPs) and PCR-based markers, such as random amplified polymorphic DNA (RAPD) and amplified fragment length polymorphism (AFLP). There are several types of genetic markers (see e.g., Mohan *et al.*, 1997; Kumar, 1999 for an in-depth analysis of genetic markers). DNA-based molecular markers are useful to plant breeders because they form the basis for marker-assisted selection. They can be tightly linked to the gene of interest, are unaffected by environmental conditions, and are detectable in all stages of plant growth (Mohan *et al.*, 1997). They can complement and speed up the classical breeding process. A cross between *A. byzantina* (cv. 'Kanota') and *A. sativa* (cv. "Ogle") was the basis of the first molecular linkage map of *A. sativa* (O'Donoughe *et al.*, 1995), and this map currently consists of more than 1000 molecular markers, including molecular marker genes linked to various oat traits of interest, such as genes for crown rust resistance (Penner *et al.*, 1993a; Bush and Wise, 1996, 1998), stem rust resistance (Penner *et al.*, 1993b), seed dormancy (Fennimore *et al.*, 1999), BYDV (Jin *et al.*, 1998), vernalization responses (Holland *et al.*, 1997), and a marker linked to dwarfing gene (Milach *et al.*, 1997).

Genomics consists of two main parts, structural and functional genomics. Structural genomics deals with mapping of genomes, sequencing, and determining where genes and regulatory regions are located on a chromosome while functional genomics studies the role, expression, and regulation of genes as well as their interactions. Attempts to sequence cultivated oat genomes are hampered by several obstacles. The cultivated oat

has a large genome size of about 1C DNA content of 1.4×10^{10} base pairs (Bennett and Smith, 1976), which is more than five times larger than human genome. This is partially due to the fact that cultivated oat is an allopolyploid, more specifically an allohexaploid containing A, C, and D genomes, as compared to rice which has a diploid genome of only 430 Mb per haploid cell (McCouch, 1998).

The amount of financial support allocated to research for a crop is often commensurate with the economic importance of that crop, and for that reason, oat research does not receive as much research dollar as do more agronomically important crops, such as rice, maize, wheat, or cotton. The scarcity of funds and the large size of oat genome are major impediments to oat biotechnology, but despite these problems, substantial progress has been made in the application of molecular tools for oat improvement. Furthermore, there is a great deal of synteny among the genomes of the members of the Poaceae family to which oat belongs. Therefore, information gathered in other cereal crops, such as rice whose entire genome has been sequenced (IRGSP, 2005; <http://rgp.dna.affrc.go.jp/IRGSP/whatsnew.html>), may be used as a proxy species for the study of oat genome. However, heavy reliance on such a practice should be avoided because the loss of synteny, though slow, is reasonably steady due to genome rearrangements (Paterson *et al.*, 2000; Gaut, 2002), in particular in hexaploid oat, which has numerous chromosomal rearrangements (O'Donoughe *et al.*, 1995; Wight *et al.*, 2003). Despite the challenges mentioned above, the future of oat biotechnology could still be bright because of the increasing amount of health benefits associated with oats. These benefits include cholesterol-lowering effects and the blood glucose and insulin-reducing responses of oat bran, which is so crucial in controlling diabetes, a disease that is increasing becoming a global epidemic health issue.

Sorghum

Hunter K.C. Laidlaw and Ian D. Godwin

School of Land, Crop and Food Sciences, The University of Queensland, Brisbane, Australia

1. INTRODUCTION

1.1 History, Origin, and Distribution

The center of diversity and origin of sorghum is in sub-Saharan Africa, extending from the Horn of Africa in the east to the west coast in present day Senegal, and south to the Cape of Good Hope in South Africa. Evidence of sorghum cultivation extends back to approximately 5000 years ago, with archaeological findings suggesting sorghum cultivation in Ethiopia, Somalia, and around the Red Sea at least 4500 years ago. Doggett (1965) considered that sorghum was first cultivated in the Ethiopian highlands and southern Ethiopia and Sudan over 5000 years ago. Cultivated landraces are now found throughout Africa.

Sorghum spread to India and China over 2000 years ago, and there is evidence for the expansion by Arab traders both by boat to the coastal areas of India, and overland across the Silk Route. Molecular and other evidences seem to indicate that the Chinese sorghum types (Kaoliang) were introduced via India, and seem to form a group with distinct characteristics, very probably derived via introgression from wild sorghums such as *Sorghum propinquum* (Doggett, 1988).

Until the late 1800s, sorghum cultivation was confined almost entirely to the African and Asian continents, and was only of any major importance in India and China. The movement

to the Americas was initially concurrent with the human slave trade from Africa, and when introduced into the United States from West Africa was originally known as guinea corn. By the late 1880s, a number of separate introductions had been made with names such as milo, durra, hegari, and kafir corn. Forage and sweet sorghums were also introduced during this time, most notably as Sudangrass and sorgo (sweet sorghum) from Natal. Sorghum remains an important crop in the middle west states of Kansas, Texas, and to a lesser extent Nebraska and Oklahoma. It was not until the 20th century that sorghum became accepted as an important crop in parts of Latin America, most notably in Mexico, Argentina, and Brazil. Sorghum has become an important part of the farming system in the northern grain belt of Australia, and is now Australia's most important summer cereal crop.

1.2 Botanical Description

Sorghum is a diploid species ($2n = 2x = 20$), and a member of the family Andropogonae. Among the cultivated grasses, it is most closely related to the *Saccharums* including cultivated sugarcane. The species is quite variable, varying in height from 50 cm to almost 6 m. Sorghum has widely been referred to as guinea corn, chicken corn, milo, feterita, and locally as kafir corn in South Africa, great millet in West Africa, jowar in India, and kaoliang in China.

Morphologically, sorghum usually has an erect, often single stem, but can be profusely tillering. The inflorescence is usually a compact panicle and although generally self-pollinating, outcrossing can be as high as 5–15%. At maturity, the seeds vary from spherical, oval or in some cases more flattened with a lentil-like shape, and are smaller than maize grains. They can be covered by glumes, but in most modern sorghums the glumes are very small, and seed coat varies from white, pale yellow, gray, red, brown through to very dark purple, or even black.

Sorghum was originally classified as *Holcus* by Linnaeus in 1753, until Moench distinguished the genus *Sorghum* in 1794. The genus is found worldwide throughout the monsoonal and semi-arid tropics, yet distribution does extend into temperate regions of Australia, such as the case of *Sorghum leiocladum*.

Sorghum bicolor is of sub-Saharan origin, and the species includes all the annual taxa of the section *Sorghum* as recognized by Snowden (1936). This includes not only the cultivated taxa, but also the variable wild African types and weedy derivatives with three recognizable subspecies.

S. bicolor subsp. *bicolor*, which includes the domesticated and improved types, has been divided into five basic races, namely, *bicolor*, *kafir*, *caudatum*, *durra*, and *guinea* (Harlan and de Wet, 1972). It is believed that the race *bicolor* originated in Ethiopia, *durra* and *caudatum* types are most dominant in Ethiopia and Sudan and the East African highlands, the *guineas* are from West Africa and the *kafirs* are from Southern Africa, predominantly Zambia, Malawi, Mozambique, Zimbabwe, and South Africa. Subspecies *drummondii* is a weedy species found almost in all places where grain sorghum is cultivated and is easily interfertile with the cultivated species. The most variable wild sorghum is the subspecies *verticilliflorum*, which includes the former subspecies *arundinaceum*, and is found across the African savanna and has been inadvertently introduced into Australia, India, and the Americas.

In its original, tropically adapted form, sorghum is a tall, photoperiod sensitive long-duration grass. It is best adapted to summer dominant rainfall areas, and flowering is usually induced as days become shorter, which usually coincides with the cessation of the rainy season.

1.3 Economic Importance

Sorghum (*S. bicolor* L.) is an important cereal crop throughout the semi-arid tropical and subtropical regions of the world. Approximately 300 million people in sub-Saharan Africa and India rely on sorghum grain as a major staple food. In many developing countries, sorghum is a multipurpose crop, with the stover widely used as forage for cattle, goats, and sheep. The grain is used for breads and porridges, and in parts of Africa it is an important component of the local beer making process, whereas in China, a major use is for high alcohol beverage distillation. Elsewhere, sorghum is important as an animal feed grain and a forage crop. The major production areas are found in Africa, Asia, and the Americas, with the major producers being the United States, Mexico, India, Nigeria, and China (Figure 1).

In addition to grain types, sorghum has had historical importance as a sweet sorghum, with the stems crushed for sweet syrup or eaten as a sweet stalk. Special forage sorghum types are grown throughout the tropics and subtropics, and may be fed as a standing crop, or harvested and fed fresh, as silage or dried as hay. In many parts of the developing world, the stover may be just as economically important as the grain. Recent interest in the sweet sorghums has focused on their potential has a high biomass feedstock for bioethanol production.

Sorghum is commonly considered as a “poor man’s crop.” This perception stems predominantly from the fact that sorghum is mainly cultivated in the more agriculturally marginal areas, and the areas of least economic development. Even in developed countries, such as the United States and Australia, sorghum is mostly cultivated in areas too hot and/or dry for reliable yields of maize or other higher value crops. Indeed, it is the adaptation of sorghum that makes it a preferable proposition in more marginal areas of production. Sorghum crops can yield under low water conditions and produces viable pollen under higher temperatures than alternative crops, such as maize, which tends to suffer from tissue damage and poor pollination under high temperatures. Sorghum is remarkably tolerant of high temperatures, with the rate of metabolic processes unaffected up to 38 °C (Ludlow and Wilson, 1971), and reversible high temperature

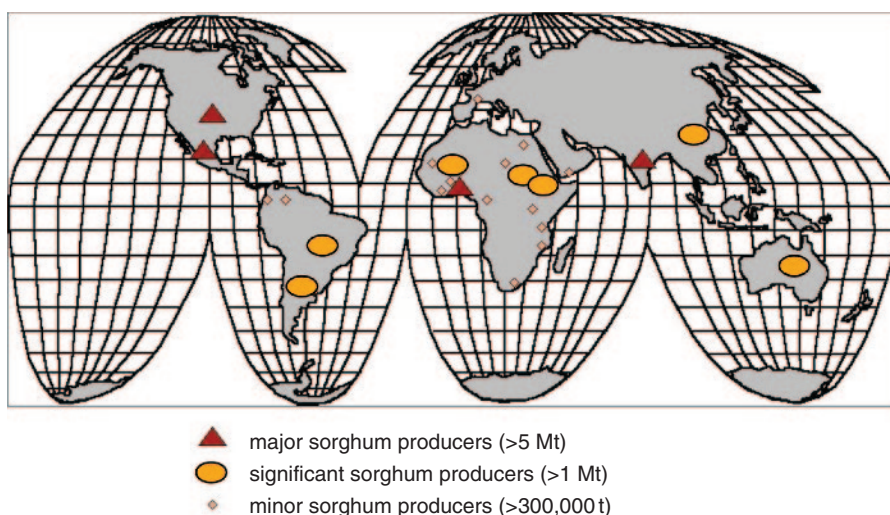

Figure 1 Important sorghum producing nations, based on annual grain production (tons) for 2005 (FAO, 2006)

damage does not occur until leaf temperature exceeds 46 °C (Ludlow, 1987).

Sorghum's lower value as a crop is a result of two factors:

1. The major food grains (wheat, rice, and maize) are preferred as food by most people, because of tradition, taste, and the variety of utilization.
2. Sorghum is less digestible to both humans and livestock than wheat, barley, maize, and oats.

In the semi-arid tropics, subsistence sorghums of Africa and South Asia generally yield 700 kg ha⁻¹ or less, with little change in yield over the last 50 years. Sorghums in these areas are commonly confined to the most marginal land with the millets, where land with higher rainfall or better soils is usually used for maize, cotton, or other higher value crops.

In the subtropical and temperate regions of the developed world, most notably in the United States, Argentina, Mexico, and Australia, average yields are substantially higher, often in excess of 3 t ha⁻¹. Better soils, rainfall distribution, and availability of hybrid seed as well as fertility and plant population management contribute to this. Average yields in the United States exceed 4 t ha⁻¹, and the major impact, as will be discussed in Section 1.4 has been of breeding programs, particularly the introduction of F₁ hybrid varieties.

1.4 Breeding Programs

As sorghum is predominantly grown in the tropical developing world, or the more marginal cropping areas of the developed nations, heat and drought remain the major abiotic stresses to production (Doggett, 1988). Much of the plant breeding focus is on maintaining production under the typical conditions of high temperature and low water availability at some stage of the summer production cycle. As with other cereals, nitrogen use efficiency is also a major issue in crop improvement and management. In tropical areas of Africa and South America, acid soils are a limitation to cereal and other grain crop cultivation, with associated problems of aluminium toxicity and phosphorus deficiency.

Worldwide, insect pests are the major biotic stress faced by sorghum producers, with an estimated grain loss well in excess of US\$1 billion annually (Nwanze *et al.*, 1995). In terms of economic damage, the most destructive pests are the lepidopterans, heliothis (*Helicoverpa armigera*), and stem borer (*Chilo partellus*, yellow stem borer) and the dipterans, midge (*Stenodiplosis sorghicola*), and shootfly (*Atherigona soccata*). Genetic sources of resistance have been combined to produce midge resistant hybrids in Australia (Henzell and Hare, 1996) and India (Sharma *et al.*, 1996), although this appears to have come at the expense of genetic variability (Jordan *et al.*, 1998).

There are no sources of true resistance to heliothis, stem borer, or shootfly.

Diseases are a constraint to both production and quality of grain and forage sorghums. Downy mildew is a major limitation to grain yield in the United States and other parts of the world (Frederikson, 1980). Other fungal leaf diseases usually do not impact greatly on grain yield, but some such as rust and leaf blight are important in reducing forage quality. Viral diseases such as Johnsongrass mosaic virus and maize dwarf mosaic virus can be particularly damaging to yield and forage quality, especially when infection occurs early in the crop cycle (Franzmann *et al.*, 1996).

Sorghum ergot, or sugary disease, is caused by two different fungi (*Claviceps sorghi*, *C. africana*). The disease has been important in Asia and Africa, and in the late 1990s, spread throughout the Americas and Australia. The disease can lead to total crop loss, and recent reports have demonstrated that the alkaloids produced by the fungus are toxic to livestock (Bailey *et al.*, 1999; Moss *et al.*, 1999). Ergot is particularly devastating to susceptible cytoplasmic male sterile parents in hybrid seed production (Meinke and Ryley, 1997; Isakeit *et al.*, 1998).

As already discussed, there has been little change in average yields in subsistence type sorghums in Africa and South Asia. Open-pollinated varieties and landraces still predominate among the cultivated sorghums in Africa. In both China and more recently India, hybrid sorghums have largely replaced the landraces or improved open-pollinated inbred varieties.

With the availability of the first commercial hybrids in the United States in 1957, sorghum productivity increased markedly. Within 4 years, most farmers had adopted the new hybrid cultivars, with the result that average yields more than doubled over this time. The original hybrids were predominantly made between East African *caudatum* and South African *kafir* types.

The United States Department of Agriculture (USDA) commenced the sorghum conversion program in the 1950s with the aim to “convert” unadapted tropical types with height of >3 m, photoperiod sensitivity and harvest indices of around 20. By the introduction of dwarfing and photoperiod insensitivity genes, the sorghums were converted to more temperate adaptation.

This involved shuttle breeding between the USDA stations in Puerto Rico and Texas, involving about five backcrosses to transfer at least eight major genes from a four-dwarf line BTx406 (Rosenow *et al.*, 1971). This particular program was instrumental in bringing into adapted breeding germplasm many traits for pest and disease resistance, as well as resistance to abiotic stresses, such as drought and soil toxicity.

2. SORGHUM TRANSFORMATION

2.1 Donor Genes

A successful transformation system typically requires the use of reporter genes, selectable marker genes (see Section 2.4), and appropriate promoters to regulate transgene expression. Promoters are regulatory sequences located upstream of a gene and determine patterns and levels of expression. Constitutive promoters direct expression in almost all tissues and function independently of developmental or environmental signals. Besides constitutive promoters, tissue-specific and inducible promoters can also be used. Several promoters have been evaluated in sorghum including those from the rice actin gene *Act1* (McElroy *et al.*, 1991), the maize *ubiquitin1* (*Ubi1*; Christensen *et al.*, 1992), and alcohol dehydrogenase-1 (*adh1*) genes, and the chimeric maize *Emu* promoter (Last *et al.*, 1991). These promoters drive strong, constitutive expression and result in significantly higher expression levels in monocotyledonous species compared with the 35S promoter from cauliflower mosaic virus (CaMV; Schledzewski and Mendel, 1994). Several reports have shown that the *Ubi1* promoter has the highest activity in sorghum compared with other promoters tested to date (Able *et al.*, 2001; Hill-Ambrose and Weeks, 2001; Jeoung *et al.*, 2002; Tadesse *et al.*, 2003). Able *et al.* (2001) ranked *Ubi1* promoter activity as highest in sorghum, followed by *Act1* then CaMV 35S. A similar trend of *Ubi1* > *Act1D* > *adh1* > CaMV 35S was also reported by Tadesse *et al.* (2003). Hill-Ambrose and Weeks (2001) examined transient β -glucuronidase (GUS) expression in embryogenic tissue and ranked the promoters as CaMV 35S \geq *Ubi1* \geq *adh1* \geq *Act1* \geq control. However, GUS activity was very low compared with expression in

similarly derived wheat callus. It was suggested that ineffective promoter strength could be one reason for low transformation rates in sorghum, and that future work should focus on the development of more effective promoters.

Several reporter genes have been used in transformation systems to monitor the efficiency of DNA transfer. These genes are also useful for monitoring the expression pattern of transformed genes in cells, tissues, or whole plants. In particular, they are useful for determining differential expression patterns of promoters in different tissues and at different developmental stages of growth. In addition, transient expression of reporter genes can be evaluated within 48h of DNA delivery. This rapid analysis can be used to assess the activity of genes or promoters without requiring stable integration of the DNA into the host genome. Ideally, reporter genes should have no detrimental effects on the plant's metabolism, there should be negligible background activity caused by the plant cells, and any assay should be sensitive and easy to carry out. The most commonly used reporter gene has been the β -glucuronidase gene (*GUS*; Jefferson *et al.*, 1987), encoded by the *uidA* locus of *Escherichia coli*. This gene meets most of the above criteria, but it does involve a destructive assay. Several groups investigating the sorghum transformation system have used this marker gene (Casas *et al.*, 1993; Emani *et al.*, 2002; Tadesse *et al.*, 2003; Girijashankar *et al.*, 2005; Howe *et al.*, 2006). Nondestructive marker systems have also been developed using the green fluorescent protein (GFP) from the jellyfish *Aequorea victoria* (Chalfie *et al.*, 1994). The *GFP* gene has also been used as a reporter gene for visual selection of transgenic sorghum plants (Gao *et al.*, 2005a) and by Gao *et al.* (2005b) in a dual-marker system with mannose selection (see Section 2.4). Both the *GFP* and *GUS* genes were tested for suitability and effectiveness for the early detection of transgene expression when optimizing an *Agrobacterium*-mediated sorghum transformation with sorghum lines C401 and Tx430 (Jeoung *et al.*, 2002). *GFP* was found to be an effective reporter gene when optimizing conditions for transient expression. Of the two sorghum lines tested, Tx430 was identified as yielding the most instances of transient expression that could be correlated with stably transformed callus lobes.

2.2 Sorghum Transformation

Biolistic and *Agrobacterium*-mediated transformation methods currently underpin the genetic engineering of sorghum. While *Agrobacterium*-mediated transformation has been used extensively with dicotyledonous plants since first reported by Zambryski *et al.* (1983), monocotyledonous plants such as sorghum were considered outside the host range (DeCleene and DeLey, 1976). Significant effort has since been directed toward the development of *Agrobacterium*-mediated transformation systems for the economically important cereals, and there are an increasing number of systems being reported for sorghum. The proposed mechanisms by which transfer DNA (T-DNA) transfer and integration occur have been extensively reviewed elsewhere (Gelvin, 2000; Tzfira and Citovsky, 2002; Valentine, 2003; Tzfira *et al.*, 2004), as have many of the factors known to influence the success of *Agrobacterium*-mediated transformation of cereals (Cheng *et al.*, 2004).

The earliest sorghum transformation studies produced transgenic calli containing the neomycin phosphotransferase (*neo*) and β -glucuronidase (*uidA*) genes following electroporation of protoplast cultures (Battraw and Hall, 1991). However, the calli were nonmorphogenic and unable to be regenerated into plants. Regeneration from embryogenic suspension culture protoplasts had been reported by Wei and Xu (1990), but significant albinism, sterility, and morphological mutations were encountered. Stable transformation of cell cultures with the hygromycin phosphotransferase (*hpt*), *neo*, and *uidA* genes via microprojectile bombardment was also reported by Hagio *et al.* (1991). In this study, only eight cell colonies were recovered on hygromycin B and three were selected on kanamycin.

The first transgenic sorghum plants were created using a Biolistics PDS 1000/He system to bombard immature embryos (Casas *et al.*, 1993). While eight sorghum genotypes were used, P898012 was the only cultivar for which transgenic plants were regenerated (from 2 out of 600 bombarded embryos). Modified methods were also used by this group to produce sorghum carrying a range of reporter genes (Kononowicz *et al.*, 1995). A particle-inflow-gun was used by Rathus *et al.* (1996) to transform embryogenic calli derived from immature embryos. This allowed

several shoots to be selected on Basta[®]-containing medium, although only a single plant survived transfer to soil. These reports were followed by the production of sorghum carrying a rice chitinase gene and the *bar* gene that were introduced into immature zygotic embryos using a biolistic PDS/He system (Zhu *et al.*, 1998). A total of 1100 calli were bombarded to obtain just six fertile transgenic plants. Subsequent work with progeny of these plants has demonstrated that those constitutively expressing the chitinase gene have improved resistance to stalk rot (Krishnaveni *et al.*, 2001). Partial tolerance to insect damage has also been reported after transforming sorghum with a synthetic *cry1Ac* from *Bacillus thuringiensis* under the control of a wound-inducible promoter (Girijashankar *et al.*, 2005).

The optimization of microprojectile bombardment parameters has been reported in the years following these first reports of transgenic sorghum. The pressure, distance to the target tissue and the aperture of the helium inlet valve were optimized for a particle-inflow-gun, and used to produce fertile, transgenic sorghum plants carrying the *bar* gene by Able *et al.* (2001). Similar parameters were also optimized by Syamala and Devi (2004) in the development of their own transformation system. Additional optimization of transformation conditions was also conducted by Tadesse *et al.* (2003). Physical parameters such as acceleration pressure, target distance, gap width, and macroprojectile travel distance were tested, with gold and tungsten, using a PDS-1000/He biolistic device. The optimized bombardment conditions were applied to produce geneticin-resistant sorghum plants from immature embryos and shoot tips. This transformation system was used to generate transgenic sorghum plants with an altered biochemical pathway for increased lysine production (Dewaele *et al.*, 2002). The same type of device was again used to introduce the *bar* and *GUS* transgenes into immature sorghum embryos (Emani *et al.*, 2002). However, the *GUS* transgene was found to have been silenced. Subsequent examination of the transgenes indicated that methylation-based silencing was involved, and it was suggested that this mechanism could be responsible for many of the cases of transgene inactivation that have been reported.

Initial work with *Agrobacterium*-mediated transformation systems allowed Godwin and

Chikwamba (1994) to generate several chimeric plants, in which histochemical GUS assays provided evidence of transgene expression but Southern hybridization failed to confirm transgenicity. The first report of transgenic sorghum displaying stable Mendelian inheritance of the transgene introduced via *Agrobacterium* was from Zhao *et al.* (2000). This involved the introduction of the *bar* gene for herbicide resistance into immature embryos of a public inbred (P898012) and a commercial line (PHI391) of sorghum. Various transformation conditions and media were tested to produce 131 stable transformation events from 6175 inoculated embryos, an overall transformation frequency of 2.1%. Reporter genes were also transferred to sorghum lines Tx430, C401 (a Chinese inbred line), and Wheatland via *Agrobacterium* by Jeoung *et al.* (2002). Subsequent reports began to identify factors that had the greatest influence on the success of transformation. Carvalho *et al.* (2004) showed these to include the sensitivity of immature embryos to *Agrobacterium* infection, the growing conditions of the donor plant, the explant type, and the composition of the co-cultivation medium. A major problem encountered in the establishment of their protocols was a necrotic response displayed by explants after co-cultivation. Attempts to minimize the hypersensitivity reactions with antioxidants that have successfully been used in other species were unsuccessful. While a transformation efficiency of up to 3.5% was achieved, a high degree of variation in transient GUS expression and immature embryo survival after co-cultivation was found in many experiments, even under similar experimental conditions. This efficiency was similar to the 3.3% achieved for the inbred line C401 by Gao *et al.* (2005b). A rapid and reproducible *Agrobacterium*-mediated transformation system has recently been reported by Howe *et al.* (2006). A combination of changes to previously reported systems was used, including a hypervirulent strain of *Agrobacterium*, the *nptII* marker gene for selection on geneticin or paromomycin, and a medium salt composition to alleviate phenolic secretion and the associated problems in tissue culture. Their protocols resulted in transformation frequencies up to 4.5%, the highest reported to date.

The choice of genetic transformation method relies on both practical and biological requirements. Particle bombardment can offer

a number of advantages over *Agrobacterium*-mediated transformation as it could, in theory, be used with any plant species. However, the insertion and integration of DNA into the host genome in a biolistic system is essentially a random process. Transgenic plants produced from bombarded explants can have very high transgene copy numbers and complex integration patterns (Register *et al.*, 1994). Multiple copy inserts are undesirable in most transgenic plants, as clusters of the same gene can increase the risk of transgene silencing and DNA rearrangement (Kumpatla and Hall, 1998; Pawlowski and Somers, 1998). In contrast, *Agrobacterium*-mediated transformation often results in the integration of a single copy of the transgene. In addition, the transferred DNA can usually be better defined, as bombardment of plasmid constructs often leads to integration of vector fragments in addition to the transgene. However, in some comparisons of *Agrobacterium* and biolistic methods, no differences have been found in the occurrence of transgene rearrangements or undesirable integration patterns (Kohli *et al.*, 1999).

2.3 Tissue Culture

Tissue culture is used to describe a variety of techniques that exploit the totipotency and plasticity of plant cells, enabling the regeneration of whole plants from small tissue pieces or single cells. These methods include micropropagation and embryo rescue, and may involve the manipulation of callus, protoplasts, cell suspensions, or anther and microspore cultures. Such procedures are conducted *in vitro*, enabling the environment and growth medium to be manipulated to ensure a high frequency of regeneration. The ability to generate fertile plants from single cells has made this technology an integral step in the development of transgenic plants.

Tissue culture methodologies have been developed for sorghum over a number of decades. Early reports described systems using embryogenic callus (Masteller and Holden, 1970), immature embryo culture (Ma *et al.*, 1987), shoot portions of mature embryos (Cai *et al.*, 1987), and somatic embryos developed from embryogenic callus (MacKinnon *et al.*, 1987). Regeneration from sorghum protoplasts (Wei and Xu, 1990) has

been reported and immature inflorescences have been shown to have embryogenic potential (Cai and Butler, 1990). Callus initiation and growth has even been obtained from transverse thin cell layers of roots or epicotyls from sorghum seedlings (Gendy *et al.*, 1996). In addition, shoot apices have been used (Bhaskaran and Smith, 1989), as have nodes (Masteller and Holden, 1970) in organogenic systems. Plant regeneration has also been reported from immature and mature sorghum embryos (Gamborg *et al.*, 1977; MacKinnon *et al.*, 1986; Bhaskaran *et al.*, 1987; Ma *et al.*, 1987; Bhaskaran and Smith, 1988; Oldach *et al.*, 2001). However, many genotypes do not readily produce regenerable calli, as embryo culture appears to be media and genotype dependent. Genetic differences were also found to affect the regenerative potential of callus derived from immature inflorescences (Cai and Butler, 1990).

An ideal tissue culture system should not induce unwanted changes into the host genome, however, dedifferentiation of plant cells that occur during a callus phase is well known to induce such changes, i.e., somaclonal variation (Larkin and Scowcroft, 1981). To avoid this, tissue culture methodologies that involve little or no callus stage have been developed using shoot apices. These methods have been reported for sorghum (Zhong *et al.*, 1998) using similar procedures as those employed for maize, barley, and oats (Zhong *et al.*, 1992a, b; Zhang *et al.*, 1996, 1999). In these systems, multiple shoots are produced through differentiation of both axillary and adventitious buds when apical dominance is removed. An additional advantage of this system is that it is less genotype specific than many of the callus systems. A range of sorghum genotypes have been trialed in this culture system and all were shown to regenerate at a relatively high frequency (Zhong *et al.*, 1998; Williams *et al.*, 2004). An additional advantage is the ability to use mature seed-derived meristems, which removes any seasonal constraints to the production of immature embryos. Despite these advances, sorghum has remained one of the more difficult cereals to manipulate for tissue culture and transformation.

Improvements and variations to the sorghum tissue culture system have been reported more recently, including revised culture media for regenerating adventitious shoots from immature embryos, thereby enabling regeneration of shoots

from up to 100% of embryos (Hagio, 2002). Manipulation of media composition and supplementation with copper and aluminium has also been shown to improve callus induction and plant regeneration (Anas and Yoshida, 2002; Gupta *et al.*, 2002; Nirwan and Kothari, 2003). There have also been further reports of the regeneration of plants from shoot apices (Harshavardhan *et al.*, 2002; Syamala and Devi, 2004). Efficient protocols that can be used with any sorghum genotype are yet to be developed and this may have delayed the utilization of transformation technologies in sorghum breeding programs, however, Sato *et al.* (2004) have recently identified an elite sorghum genotype that exhibits efficient induction of embryogenic tissue and plant regeneration.

2.4 Selection Systems

Genetic transformation systems rely on an ability to differentiate transformed and nontransformed cells, as only a small proportion of cells will have the transgenic DNA integrated into the nucleus in a stable manner. To select the desired cells, a selectable marker gene is often used, such as one that confers resistance to an antibiotic or herbicide. In recent years, there has been a move away from the use of herbicide and antibiotic resistance genes, due to the public concern over perceived safety issues and the impact that such agents could have on the environment and human health. These perceptions include potential allergenicity and the transfer of antibiotic resistance to human pathogens. In addition, sorghum is able to outcross with Johnsongrass (*Sorghum halepense*), thus presenting a route by which bialaphos herbicide resistance could be passed to this weedy species (Arriola and Ellstrand, 1996, 1997). For these and other reasons, alternative selectable marker gene systems are being developed.

Sorghum transformation systems have commonly used the phosphinothricin acetyltransferase gene (De Block *et al.*, 1987; Thompson *et al.*, 1987) as a selectable marker. This gene confers resistance to the herbicidal compound bialaphos. Kanamycin and hygromycin have also been used by Hagio *et al.* (1991) as selectable markers with sorghum suspension cell cultures. However, it was found that sorghum cells had a high level of basal tolerance to kanamycin. The

bialaphos resistance gene (*bar*) was derived from *Streptomyces hygroscopicus*, which produces the tripeptide antibiotic bialaphos. The two L-alanine residues of bialaphos are removed from the compound by intracellular peptidases, leaving the phosphinothricin compound that is a strong inhibitor of glutamine synthetase (De Block *et al.*, 1987; Thompson *et al.*, 1987). This enzyme is essential for assimilating ammonia in plants and as such, plays a key role in nitrogen regulation. The inhibition of glutamine synthetase results in the accumulation of ammonia in the plant cell and ultimately cell death.

A more recent report has presented a selection system that uses galactose as the selective agent and a UDP-glucose:galactose-1-phosphate uridyltransferase gene as the selective gene (Joersbo *et al.*, 2003). This system avoids the use of herbicide and antibiotic resistance genes, and is based on conventional selection principles. Galactose is toxic to a broad range of plant species, and the system presented by Joersbo *et al.* (2003) sufficiently reduces the toxicity of galactose to allow transformed shoots to survive on selective media, while killing any nontransformed shoots.

Alternative selection systems have now been developed in which the growth and vigor of transformed cells is favored over nontransformed cells that are outgrown or starved, but not killed as they would be in lethal selection systems (Joersbo and Okkels, 1996). These systems include the use of phosphomannose isomerase (Joersbo *et al.*, 1998), xylose isomerase (Haldrup *et al.*, 1998b), and the novel use of GUS (Joersbo and Okkels, 1996). In addition to addressing some of the environmental and safety issues, positive selection systems offer a number of advantages over the use of herbicide and antibiotic selection systems. Primarily, cells transformed with the marker gene are able to utilize a compound that can be included into the tissue culture medium, resulting in enhanced growth of the transformed cells. However, nontransformed cells remain unaffected and less able to influence the growth of any transformed cells. This influence may be present in lethal selection systems, where dead or dying cells may release toxins or other substances detrimental to the growth of transformed cells, such as phenolic compounds. The dead cells may also form a partial or complete barrier between the culture medium and any transformed cells, thus inhibiting

or slowing the uptake of nutrients and hormones by the cells.

One positive selection system has been developed using phosphomannose isomerase (PMI; EC 5.3.1.8), which catalyses the conversion of mannose-6-phosphate to fructose-6-phosphate. In the PMI selection system, plants are transformed with the PMI gene (*manA*) from *E. coli* (Miles and Guest, 1984). They are then grown on media containing mannose, a hexose sugar that is readily absorbed and converted to mannose-6-phosphate by hexokinase, but which is not metabolized further by untransformed cells. In transformed cells, the PMI enzyme can convert it to fructose-6-phosphate, which is a metabolizable sugar. The use of the *PMI* gene to select transformed cells on media containing mannose has been reported for sorghum (Gao *et al.*, 2005b) and several other cereals, including maize (Evans *et al.*, 1996; Negrotto *et al.*, 2000; Wang *et al.*, 2000; Wright *et al.*, 2001), wheat (Reed *et al.*, 1999; Wright *et al.*, 2001), and rice (He *et al.*, 2004). Gao *et al.* (2005b) reported the successful dual-marker transformation of sorghum with *PMI* and *GFP* using an *Agrobacterium*-mediated transformation system. While the reported transformation frequencies were between 2.88% and 3.30%, further optimization of this system may offer the potential for reaching the high frequencies similar to those reported for maize (30%, Negrotto *et al.*, 2000).

2.5 Regeneration Systems

Cells that survive the transformation and selection processes are regenerated through the tissue culture system into plantlets that can be transferred to soil. Once in a glasshouse and growing vigorously, the presence of transgenes can be confirmed using a number of rigorous molecular techniques. While a number of studies have been conducted in sorghum to optimize the efficiency of genetic transformation (Able *et al.*, 2001; Tadesse *et al.*, 2003), little attention has been given to improving the survival rate of sorghum plants when transferred from *in vitro* culture to the open environment. Low efficiency during this stage of the transformation system can result in substantial losses of putatively transgenic plants.

It is well established that plantlets cultivated *in vitro* suffer from a range of morphological abnor-

malities. During the acclimatization period, several changes in leaf structure, water relations, and photosynthesis take place and these modifications can often be accelerated using antitranspirants and elevated CO₂ concentrations (reviewed by Pospíšilová *et al.*, 1999). A wide variety of methods have been used to acclimatize sorghum plants from all types of tissue culture before transfer to the glasshouse (Table 1). Many differences exist among the soil substrates, environmental conditions, and time frames used in each phase of the process. There is also great variation in the clarity with which these conditions are described. The efficiency of the systems has not always been recorded, however, Smith *et al.* (1983) reported that many of the rooted plants did not survive transfer, while Zhu *et al.* (1998) reported that only 60% of plants survived transplantation to soil.

We have previously reported on the generation of organogenic tissue cultures derived from the meristem of germinated sorghum seeds (Williams *et al.*, 2004). After observing considerable variation in the success of our hardening-off methods and those reported in the literature, we examined simple ways to improve the frequency of plantlet survival. Once plantlets had developed roots to between 15 and 30 mm in length, they were removed from the *in vitro* environment and at least 15 plantlets were transplanted into a variety of sterile substrates:

- A. seed raising mix in 50 mm pots with a clear plastic bag cover that was progressively opened and ultimately removed after 2 weeks;
- B. potting mix based on UC mix B;
- C. grade 2 vermiculite;
- D. 2:1 grade 3 vermiculite:sand;
- E. 4:1 perlite:grade 2 vermiculite, or;
- F. a filter-paper bridge in 10 mL of half-strength liquid culture medium in a glass test tube for 2 weeks before transfer into grade 2 vermiculite.

Liquid fertilizer (1 g l⁻¹ Aquasol™) was used to moisten the solid media once a week and sterile water was used as required between these times. One to two weeks after transplant, the lids of the culture vessels were progressively opened over the course of several days. Plants were retained in the tissue culture room until they were growing vigorously and their roots had reached 1–2 mm in diameter and new leaf

Table 1 Hardening-off conditions reported for sorghum plants derived from diverse tissue types

Tissue type (source)	Photo-period (h)	Light intensity ($\mu\text{Mm}^{-2} \text{s}^{-1}$)	Substrate	References
Callus (immature embryos)	20	27	Vermiculite:sand: peatmoss mixture	Gamborg <i>et al.</i> (1977)

	–	–	Soil	Zhu <i>et al.</i> (1998)
	16	30	Soil mix (nonsterile)	Able <i>et al.</i> (2001)
	16	70	Soil	Oldach <i>et al.</i> (2001)
	16	80	–	Hagio (2002)
Embryos and callus (immature embryos)	16	270	Universal mix	Zhao <i>et al.</i> (2000)
	–	50 or 120	Peatmoss mixture	Carvalho <i>et al.</i> (2004)
Callus (immature embryos and immature inflorescences)	16	13.5–27	–	Kononowicz <i>et al.</i> (1995)
Inflorescence (immature, unemerged)	16	4.7 or 40.5	Soil	Brettell <i>et al.</i> (1980)
Shoot tips, callus, and embryos (immature and mature)	16	43	1:1 soil:vermiculite (sterile)	Tadesse <i>et al.</i> (2003)
Callus (shoots of germinating seed)	16	24	Vermiculite	Smith <i>et al.</i> (1983)
	16	27	Vermiculite (sterile)	Bhaskaran <i>et al.</i> (1983)
Callus (mature embryos)	–	–	Soil-less potting mixture	Duncan <i>et al.</i> (1995)
	16	25	1:1 soil:compost	Nirwan and Kothari (2003)
Shoot apical meristems (excised 24 h after germination)	18	–	3:1 field soil and vermiculite (sterile)	Nahdi and de Wet (1995)
Shoot apices (excised 7 day after germination), somatic embryos (shoot apices)	16	–	1:1 soil:coconut peat (sterile)	Syamala and Devi (2003)
Shoot apices (excised 7 day after germination)	24	30	1:1 peat:perlite	Zhong <i>et al.</i> (1998)
	16	–	Vermiculite mixture (sterile)	Girijashankar <i>et al.</i> (2005)

blades had a width of more than 10 mm, approximately 4–5 weeks after transplant. The light intensity in the culture room was increased from $25 \pm 5 \mu\text{Mm}^{-2} \text{s}^{-1}$ during organogenic culture production to $80 \pm 10 \mu\text{Mm}^{-2} \text{s}^{-1}$ after rooting. Plants were transferred to the glasshouse for acclimatization for 1 week in their same vessel before being transplanted into 100 mm pots of UC mix. The survival of plants was assessed after 6 weeks in the glasshouse (Table 2). Analysis of the results, conducted with the λ^2 -test of independence (Minitab, R14; with a significance level corresponding to p -value < 0.05), demonstrated that there was a significant effect of the soil substrate on survival. The seed raising mix, vermiculite:sand and perlite:vermiculite substrates

Table 2 Survival of sorghum plants after transfer from tissue culture^(a) into various substrates

Substrate	Survival rate ^(a) (%)
(A) Seed raising mix	19
(B) Potting mix	87
(C) Vermiculite	76
(D) Vermiculite:sand	0
(E) Perlite:vermiculite	100
(F) Filter-paper bridge in liquid media	33

^(a)Plant survival was assessed 6 weeks after transfer to the glasshouse

were found to contribute the most to these differences (Table 2).

The use of these substrates, combined with a higher light intensity after rooting, produced

plants that were more robust and vigorously growing before transfer to the glasshouse, where they quickly adapted to the changed environment. The transfer of plants from tissue culture to soil media is an integral step in any plant transformation process. High survival rates during this critical transition to *ex vitro* conditions are particularly important if transformation frequencies are low. Significant improvements can be made to the survival rate of regenerated plants and it is hoped that this will contribute to improved transformation efficiency for sorghum.

3. THE FUTURE OF SORGHUM TRANSGENICS

3.1 Potential Products

There are currently three major targets for sorghum improvement via genetic modification, these being the improvement of nutritional quality, pest resistance, and disease resistance. Sorghum pests will continue to be targeted with a transgenic approach, such as that reported by Girijashankar *et al.* (2005) who used a synthetic *cryIAc* gene against stem borer. Sorghum yield and quality is also affected by many diseases (e.g., more than 50 have been identified in Australia; Ryley *et al.*, 2002), which can cause serious economic losses and endanger food security for a significant proportion of people in tropical and subtropical areas of the world who are reliant on sorghum. Many of the diseases of global importance are caused by fungi, including grain molds, stalk rots, ergot, smuts, anthracnose, and downy mildew (de Milliano, 2002). In Australia, ergot (caused by *C. africana*) is a major disease, which has a significant impact on all sectors of the industry, particularly hybrid seed production (Ryley *et al.*, 2002). Sorghum rust (caused by *Puccinia purpurea*) and leaf blight (caused by *Exserohilum turcicum*) are serious leaf diseases that result in direct yield losses. Sorghum rust is a pathogen found in most sorghum production areas of the world. Recurrent periods of wet and cool weather during the early vegetative growth stage can lead to a high incidence of the disease. The resulting high infection levels during flowering and early grain fill can have a serious impact on yield, and due to the decreased

photosynthetic leaf area, plants can be predisposed to lodging (Ryley *et al.*, 2002). Globally, the disease itself has little effect on sorghum yield, but infection by the fungus predisposes the plant to other more significant diseases such as grain molds, charcoal, and *Fusarium* stalk rots. Some reports have estimated grain yield losses up to 65% under conditions favorable for disease development (Bandyopadhyay, 1986). Host disease resistance genes typically provide defense against rust infection and a rust resistance gene has been identified in sorghum (Ramakrishna *et al.*, 2002; McIntyre *et al.*, 2004), which is a homolog of the extensively studied *Rp1-D* rust resistance gene from maize. The use of maize resistance genes in other cereal species has been investigated by Ayliffe *et al.* (2004) who generated transgenic wheat and barley with the *Rp1-D* gene. The ability to use resistance genes, particularly highly characterized ones such as these from maize, to control a range of pathogens in related species would have obvious benefits for increasing the production potential of these crops. The potential of the maize *Rp1-D* gene has been investigated as a source of novel resistance against rust pathogens in sorghum (Williams *et al.*, 2002).

Johnsongrass mosaic virus (JGMV) also occurs throughout the sorghum growing regions of Australia, particularly where the alternate host Johnsongrass (*S. halepense*) is common. JGMV is a single-stranded positive sense RNA virus of the genus *Potyvirus* (family Potyviridae), which infects sorghum, maize, and other species of Poaceae (Shukla and Teakle, 1989; Gough and Shukla, 1993). It causes a range of symptoms including mosaic, temperature-independent necrosis, stunting, delayed flowering, panicle necrosis, small seed, and reduced grain quality (Persley *et al.*, 1986). Resistance to JGMV has been a target of the sorghum breeding programs in Australia, and several lines have been developed that display mild symptoms and low levels of infection (Ryley *et al.*, 2002). However, as JGMV has previously overcome host resistance, preliminary work for the development of transgenic resistance has been undertaken. This included an assessment of the sequence diversity of the coat protein coding region of the virus (Laidlaw *et al.*, 2004), which suggested that a transgenic approach could be used to provide effective resistance against this pathogen.

The nutritional quality of sorghum, specifically the protein quality, and vitamin and mineral content, has become the focus of international research. Significant funding has been provided by the Bill and Melinda Gates Foundation to several institutions involved in the African Biofortified Sorghum (ABS) project. Their aim is to generate transgenic sorghum with increased levels of lysine, threonine and tryptophan, vitamins A and E, iron, and zinc (<http://www.supersorghum.org>). Various strategies have been developed to manipulate seed proteins, including modification of the protein sequence, metabolic engineering of free amino acids, generation of synthetic proteins, and expression of heterologous proteins. For example, amino acid synthesis pathways can be altered to preferentially accumulate a target amino acid (Sun and Liu, 2004). Much of the research reported to date has used cereal storage protein genes to improve the amino acid balance in noncereal crops. For example, maize γ -zein gene has been expressed in soybean to significantly increase cysteine and methionine content (Li *et al.*, 2005). As the maize and sorghum storage proteins (prolamins) are related, opportunities may exist to transfer some of this work to sorghum improvement. There is also potential to overexpress prolamins with high methionine and low cysteine content, such as the recently characterized δ -kafirin (Izquierdo and Godwin, 2005) to improve the methionine content of cereal and pulse crop seed storage proteins. Lysine is another essential amino acid for humans and monogastric livestock and it is the most limiting amino acid in cereal seeds. A number of approaches have been investigated to improve the lysine content in maize (Mazur *et al.*, 1999; Ferreira *et al.*, 2005). Since the isolation of the *opaque-2* mutant (*o2*; Mertz *et al.*, 1964) and the realization that the increase in lysine-rich proteins in the endosperm resulted from a decreased synthesis of 22-kD α -zeins, the trait has also been associated with low seed density and soft grain texture, leading to brittleness and increased susceptibility to insect damage. Maize germplasm that incorporates the *o2* protein quality without these detrimental problems has been developed (Quality Protein Maize; reviewed by Gibbon and Larkins, 2005). RNA interference (RNAi) technology has also been used to reduce the 22-kDa α -zeins in maize (Segal *et al.*, 2003). Instead of relying on the recessive *o2* mutation that only affects a subset of the α -zeins, an RNAi

construct was developed to produce a dominant mutation to suppress all α -zeins, without affecting the accumulation of other storage proteins. In addition, it led to increased lysine content in the grain, while reducing the levels of leucine, alanine, and glutamine. Huang *et al.* (2004) also used sense and antisense genes to reduce the expression of 19-kDa α -zeins, which led to increases in the level of lysine, tryptophan, and methionine in transgenic hybrids. The isolation and partial characterization of enzymes involved in lysine catabolism in sorghum seeds by Fornazier *et al.* (2005) is another important step toward a better understanding of lysine metabolism. The ability to alter the amino acid balance using these types of technology will be useful for manipulating the amino acid balance and further characterization of the storage protein genes in sorghum. Additional strategies for manipulating protein, mineral, and vitamin content in sorghum have been reviewed by O'Kennedy *et al.* (2006).

3.2 Improved Transformation Technologies

Significant efforts have been made to understand the mechanisms involved in *Agrobacterium*-mediated transformation in an effort to overcome some of the barriers that were preventing its routine use in the generation of transgenic cereals. For example, improvements in the efficiency of DNA transfer to rice were observed in the presence of a mutation in a virulence gene regulator that allowed constitutive expression of the *vir* genes (Ke *et al.*, 2001). Analysis of T-DNA transfer events in barley and wheat has also revealed that they occur preferentially in distinct anatomical regions of the cereal embryo that have a low capacity for regenerative growth (Ke *et al.*, 2002). Manipulation of *Agrobacterium* inoculum density and/or media composition has also been shown to alter the number and distribution of T-DNA transfer events, with the potential for a corresponding improvement of the transformation frequency. Efforts have also been made to understand and manipulate the host plant, rather than attempting to improve transformation efficiency by altering *Agrobacterium* or the inoculation conditions. For example, a population of *Brassica oleracea* segregating for transformation efficiency has been subjected to quantitative trait analysis, leading to the identification of genomic regions

that account for 26% of the observed variation (Cogan *et al.*, 2002). Several plant genes involved in *Agrobacterium*-mediated transformation have also been identified, and there is evidence that their overexpression in recalcitrant species may lead to marked improvements in transformation ability (recently reviewed by Gelvin, 2003).

The transformation of plants with large DNA fragments is also developing as a useful technology for genetic analysis and metabolic engineering in plants. One significant report by Song *et al.* (2004) demonstrated the introduction of a 90 kb bacterial artificial chromosome (BAC) clone from sorghum into maize via particle bombardment. The BAC clone consisted of ten tandem copies of the 22-kDa α -kafirin gene and neighboring genomic sequences. It was demonstrated that the entire kafirin gene cluster could be integrated into the maize genome as a single fragment and that tissue-specific expression and processing of the kafirins occurred in the maize endosperm. The ability to perform such transformations will enhance the analysis of promoters and transcription factors in their native chromosomal framework and provide another tool for functional genomics studies in the cereals. It should also be useful for transferring multigene transformation constructs for modifying complex traits and the manipulation of entire metabolic pathways. The release of the first draft of the sorghum genome sequence in 2007 has provided an important resource for the sorghum research community and anyone interested in cereal genetics (<http://www.phytozome.net/sorghum>).

3.3 Addressing Risks

It is essential that the potential impact of transgenic sorghum is assessed before release into the environment, whether in field trials or into the crop production system. Of particular concern is the ability of sorghum to hybridize with its weedy relative Johnsongrass (Arriola and Ellstrand, 1996, 1997). This provides an opportunity for transgenes to “escape” from sorghum into Johnsongrass. It is therefore important that the types of transgenes used will not confer a genetic advantage to related weeds if and when outcrossing occurs. The use of herbicide-resistant selectable markers is of particular concern, as these genes may have the potential to increase the weediness of

sorghum relatives and sorghum itself. A recent risk assessment of transgenic sorghum in Africa found that there is strong evidence that introgression of transgenes into sorghum crops and wild relatives will occur (Schmidt and Bothma, 2006). In effect, the question to pose may be not whether transgene “escape” will occur, but what the likely impact of the transgene will be. This is more effectively viewed on a gene-specific basis.

In preparation for the release of transgenic sorghum outside of the controlled laboratory and glasshouse environment, transformation systems with alternative selection strategies have been developed, such as the use of mannose in the PMI system (see Section 2.4). It is considered unlikely that the transfer of the *manA* gene to Johnsongrass would confer any adventitious traits to this weedy relative. In addition, a recent safety assessment of PMI has found no adverse effects with respect to mammalian toxicity and allergenicity, or any unintended effects on the agronomic or nutritional qualities of maize (Privalle *et al.*, 2000). There is also the possibility for other systems to be used in sorghum transformation system, such as those based on xylose isomerase and benzyladenine N-3-glucuronide. The *xylA* gene from *Thermoanaerobacterium thermosulfurogenes* encodes for xylose isomerase (EC 5.3.1.5), which catalyses the isomerization of D-xylose to D-xylulose, and has been used to successfully transform potato, tobacco, and tomato (Haldrup *et al.*, 1998b). It was found that this selection system gave up to eightfold higher transformation frequencies compared to kanamycin-based selection in potato. At the time of the publication, the selection system was not yet optimized for use with tobacco and tomato cultures. However, the frequency of transformation in tomato was increased by 20%, but was reduced by 30% in tobacco compared to a kanamycin system. In addition, Haldrup *et al.* (1998a) found that potato had endogenous xylose isomerase activity, which they used to support the harmlessness of this protein. The enzyme is also used in the food industry to produce high-fructose syrup from glucose (Quax, 1993). While, this system was not fully optimized for any of the plant species examined, it appeared to present significant advantages for use as a selectable marker system compared with existing systems. An additional selection system, based on benzyladenine N-3-glucuronide, relies on the requirement for cytokinin to obtain

favorable shoot regeneration from explants. In this system, the cytokinin is added as an inactive glucuronide derivative (benzyladenine N-3-glucuronide), which is converted to an active cytokinin (benzyladenine) through the hydrolyzing action of GUS (Joersbo and Okkels, 1996). This enzyme, encoded for by the *GUS* gene, is more commonly known for its visual transformation marker properties. Joersbo and Okkels (1996) reported up to threefold higher transformation frequencies compared to kanamycin selection systems. In addition to being a positive selection system, the GUS gene could be used as both a selectable and screenable marker. Alternatively, a number of cases of marker-free transgenic systems have also been reported which may have utility in sorghum (Sugita *et al.*, 2000; Jacob and Veluthambi, 2002; Zuo *et al.*, 2002; Permingeat *et al.*, 2003).

A number of concerns have also been raised in regard to the transformation systems used. There are reports that sequences from outside the T-DNA regions can be transferred to the host organism (Ramanathan and Veluthambi, 1995). De Buck *et al.* (2000) also showed that T-DNA vector backbone sequences were frequently integrated into the genome of transgenic plants following transformation with *Agrobacterium*. However, functional plant analogs of T-DNA border sequences have been identified in potato and rice, allowing genetically modified plants to be created using only native plant DNA (Rommens *et al.*, 2004). This advance addresses one significant objection that some consumers have toward genetically modified organisms, that is, the introduction of foreign or bacterial DNA into food crops.

The genetic modification of plants occurs within a strict framework provided by national regulatory bodies, such as the Australian Office of the Gene Technology Regulator (<http://www.ogtr.gov.au>). The regulatory powers of such bodies were demonstrated in 2006 when South Africa's biotechnology Executive Council rejected an application by the country's largest science research organization Council for Scientific and Industrial Research to conduct experiments with transgenic sorghum until more suitable containment measures were established (ABS Consortium, 2006). The development of transgenic sorghum is being undertaken within a highly regulated environment to ensure

the safety of the environment and end users. Improvements in transformation technology and our understanding of the sorghum genome are also contributing to the development of these improved sorghum lines and in so doing, helping to make transgenic sorghum a beneficial, acceptable and safe option for the plant breeder, grower, processor, and end user alike.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Pearl millet (*Pennisetum glaucum* (L.) R. Br.) is a staple food that supplies a major proportion of calories and protein to large segments of the populations living in the semi-arid tropical regions of Africa and Asia. Pearl millet was domesticated from wild grasses of the southern Sahara approximately 4000 years ago. Soon after its domestication, it spread from its homeland to East Africa and then to India. It has since become widely distributed across the semi-arid tropics of Africa and Asia. Pearl millet was first introduced into Europe in approximately 1566 where plants were grown in Belgium from seed received from India. This millet is sometimes referred to as *Pennisetum spicatum*, and is still grown in Spain and North Africa (National Research Council, 1996). Pearl millet was introduced into the United States as long ago as 1850, and is still extensively grown as a summer annual grazing crop in the south (Hanna, 2000).

1.2 Botanical Description

Pearl millet is an erect annual plant that ranges in height between 50 and 140 cm. Flowers are arranged around a cylindrical spike (8–140 cm in

length), and are yellow to green in color. The flowers are either self- or cross-pollinated. Cross-pollination occurs when the stigma emerges before anther maturation. Grain develops within 20–30 days after pollination, and seed color ranges from white to brown, and even purple. Grain is usually tear shaped, approximately 8 mg in weight, and usually smaller than wheat seed.

Pearl millet is generally a short-day plant, but breeding has produced some day-length neutral varieties. It tolerates a range of rainfall conditions depending on the variety, and is usually found growing in areas that receive between 250 and 700 mm rainfall per annum. Although pearl millet is considered to be drought tolerant, it requires an even distribution of rain over the growing season. Too much rain during flowering can lead to crop failure. The flowering and seedling stages are sensitive to low temperatures, but high day-time temperatures (typically 30 °C) are required for the grain to mature. Drought tolerance is attributed to rapid growth, a short life cycle, high temperature tolerance, and a deep root system that can reach to the soil layers untapped by other plants.

Pearl millet has an abundant natural diversity with approximately 140 species or subspecies belonging to the genus *Pennisetum* (Stapf and Hubbard, 1934; Brunken, 1977). The presence of many weedy relatives leads to cross-pollination between cultivated pearl millet and wild *Pennisetum* species, which often causes a drop in

production capacity. However, hybridization with and introgression from wild relatives often lead to new improved crop forms. Pearl millet breeding programs often take advantage of desirable traits in wild species to improve cultivated varieties. Such traits include disease and insect resistance, high yields under adverse conditions, apomixis, early maturity, and a range of morphological characteristics (National Research Council, 1996). Useful wild *Pennisetum* species for introgression of genes into pearl millet include *P. purpureum* (napier grass), *P. squamulatum*, *P. orientale*, *P. flaccidum*, *P. setaceum* (Dujardin and Hanna, 1989b), and the wild pearl millet species *P. glaucum* subsp. *monodii* and *P. glaucum* subsp. *stenostachyum*. Subspecies *monodii* has been a particularly useful source of germplasm for introgression of resistance to rust, *Pyricularia* leaf spot, and smut, as well as forage dry matter yield and seasonal distribution (Hanna, 2000).

In recent years, considerable advances have been made in the understanding of the genetics of the crop. *P. glaucum* is an annual, sexual diploid ($2n = 2x = 14$) with a haploid DNA content of 2.4 pg (picogram). However, many genetic states can be obtained, and different *Pennisetum* species have chromosome numbers in multiples of $x = 5, 7, 8$, and 9 . Furthermore, for each of these states, there are different ploidy levels. Detailed genetic maps of pearl millet of some 300 loci spread over 7 linkage groups are available (Liu *et al.*, 1994). An extended map from multiple crosses incorporates not only molecular markers but also significant phenotypic traits (Devos *et al.*, 2006). Despite these advances, pearl millet is poorly supported by science and politics. Over the past two decades, production in West Africa has increased only by 0.7% per year, the lowest growth rate of any food crop in the region (National Research Council, 1996). Over the decades, more and more farmers, especially in southern Africa, have abandoned pearl millet farming and switched over to maize. This is due to a number of reasons. First, research efforts have made maize more productive than pearl millet; second, government incentives have given maize an added financial advantage; and finally, easier processing has made maize more convenient to use. However, with water steadily becoming a limiting resource to numerous economies, pearl millet could resurge as a vital multipurpose crop.

1.3 Economic Importance

In 2003, pearl millet was the world's sixth largest cereal crop with 29 million metric tons produced on 36 million hectares of cultivated land (<http://apps.fao.org/>). Approximately half of the world's pearl millet is grown in Africa, with the continent producing 14 million metric tons in 2003 (<http://apps.fao.org/>). In southern Africa, the commercialization of agriculture has resulted in maize partially or completely displacing pearl millet as a traditional food crop. In South Africa, only 12 000 t of pearl millet was produced in 2003, and this was mainly for subsistence purposes. Almost all millet is produced by small-scale farmers for household consumption and localized trade.

Pearl millet is a crop of vital importance to millions of African families living in semi-arid regions of the continent. Millet is one of the world's most resilient crops. In many areas where millet is the staple food, nothing else will grow. Pearl millet is supremely adapted to heat and aridity and production is likely to increase as the world gets hotter and drier. Of all the major cereals, it is the one most able to tolerate extremes of heat and drought. It yields reliably in regions too hot and too dry to consistently support good yields of maize or even sorghum. Pearl millet is easy to grow and suffers less from disease and insect pests than sorghum, maize, or other grains (National Research Council, 1996).

Pearl millet grain is nutritious, and has higher protein and energy levels than maize or sorghum (National Research Council, 1996). Carbohydrates usually make up about 70% of the dry grain, and they consist almost exclusively of starch. The grain contains at least 9% protein and a good balance of amino acids. It has roughly twice the fat content (5–7%) that of most standard cereals, and is particularly high in calcium and iron. The vitamin values of pearl millet grain are generally somewhat lower than those of maize, although the levels of vitamin A and carotene are good, particularly for a cereal. Importantly, it has neither the tannins nor other compounds that reduce digestibility in sorghum. Pearl millet is a versatile foodstuff, and is mainly used as whole seed, cracked seed, ground flour, dough, or a grain like rice. These are made into unfermented breads (*roti*), fermented foods (*kisra* and *gallettes*), thin

and thick porridges (*toh*), steam cooked dishes (*couscous*), nonalcoholic beverages and traditional beers. Grain from certain cultivars is roasted whole and consumed directly (<http://africancrops.net>). Although grain is the most important consumable from pearl millet in developing countries, the crop also provides forage/silage, building materials, and fuel (Devos *et al.*, 2006). Its primary use in industrialized countries is as forage, but interest in grain production for animal feed is increasing (Andrews *et al.*, 1996).

1.4 Traditional Breeding

The semi-arid tropics are characterized by unpredictable weather, limited and erratic rainfall and nutrient-poor soils, and suffer from a host of agricultural constraints (Sharma and Ortiz, 2000; Maqbool *et al.*, 2001). There is an urgent need to focus on improving crops relevant to the small farm holders and poor consumers in the developing countries of the humid and semi-arid tropics (Sharma *et al.*, 2002).

Traditional plant breeding methods have made, and will continue to make, important contributions toward meeting the need for more food. Breeding objectives for pearl millet include tolerance to drought, enhanced nutritional quality, adaptation to saline conditions, stover feeding value, high tillering, and resistance to major pearl millet diseases such as downy mildew (*Sclerospora graminicola*), ergot (*Claviceps fusiformis*), smut (*Moesziomyces penicillariae*), rust (*Puccinia substriata*), and head mold of pearl millet. The latter diseases are more serious on commercial F₁ hybrids than on open-pollinated varieties.

Although pearl millet is regarded as an “orphan” crop, the development of molecular marker systems and molecular marker-based genetic maps was initiated early, in 1990, within a Department for International Development (DfID)-funded program (Bertin *et al.*, 2005). Pearl millet genome mapping and molecular breeding were reviewed by Devos *et al.* (2006). Specific achievements are highlighted below.

In many areas of the world, staple foods lack certain essential nutrients even though enough energy is available from these food crops. Micronutrient-rich pearl millet cultivars are being bred by the International Crops Research Institute for

the Semi-Arid Tropics (ICRISAT) to address micronutrient deficiency in the semi-arid tropics with funding support from HarvestPlus (Rao *et al.*, 2006; www.harvestplus.org). Plant breeders are aware of the need to improve not just the grain component but also the quantity and nutritive value of the vegetative part of the crop, especially where it is an important animal feed (Zerbinia and Thomas, 2003). An initiative to improve pearl millet grain carotenoid content with marker-assisted selection is underway with team members from Cornell University, University of Georgia, ILRI and Waite Institute in Australia (www.icrisat.org). A panel of genotypes (including the best-known sources of elevated grain β -carotene levels) having diverse grain characteristics are used to assess single nucleotide polymorphism (SNP) diversity in genes for enzymes controlling the carotenoid biosynthesis pathway and to establish a near-infrared spectroscopy (NIRS) calibration curve for grain β -carotene content. The development of mapping populations based on crosses of best-known trait sources and elite inbred lines will follow.

The general complexity of drought stress is aggravated in the semi-arid tropics and subtropics by highly unpredictable rainfall, and by high temperatures, high levels of solar radiation, and low soil fertility (Serraj *et al.*, 2005). The resulting large variability in the nature and occurrence of drought stress and our insufficient understanding of its complexity have made it generally difficult to identify the physiological traits required for improved crop performance under drought stress conditions. Improving the adaptation or enhancing tolerance of pearl millet to drought stress, one of the most common and serious environmental constraints, is an important objective in most pearl millet breeding programs (Yadav *et al.*, 2004; Devos *et al.*, 2006) as it reduces mean yields, increases the magnitude of the annual variation in harvests, and the incidence of crop failure. In addition, tremendous variation in the timing and in the severity and duration of drought stress, and the high degree of interaction between the timing and intensity of the stress, and the crop growth stage and genotype are prevalent in drought-prone environments. Quantitative trait loci (QTL) mapping dissects complex phenotypic characters, such as drought tolerance, into their component traits (Yadav *et al.*, 2004) and subsequently allows

the identification of molecular markers linked to desirable QTLs, so that these can be directly used in marker-assisted selection. A genetic linkage map to detect genomic regions associated with grain and stover yield, and aspects of drought tolerance, was constructed (Yadav *et al.*, 2004) to aid breeding programs. Serraj *et al.* (2005) showed that superior grain yield performance of the introgression line hybrids was accompanied by increased biomass yields and reduced grain harvest indices instead of the reduced biomass yield and increased grain harvest index that appears to contribute to the higher grain yield potential and superior terminal drought tolerance of hybrids of donor parent PRLT 2/89-33 and the QTL-based topcross pollinator.

S. graminicola, an obligate biotrophic oomycetous fungal phytopathogen, is a widespread and destructive disease of pearl millet in India and in African countries (Singh and Talukdar, 1998) and losses up to 30% amounting to 260 million US dollars are reported (Singh *et al.*, 1993; Shetty and Kumar, 2000). Although *S. graminicola*, the causal agent of downy mildew in pearl millet can be chemically controlled, host-plant resistance provides a more attractive and cost-efficient method of disease management (Devos *et al.*, 2006). Mapping QTLs for downy mildew resistance in pearl millet has been done (Jones *et al.*, 1995, 2002). Recently, Hash *et al.* (2006) have shown the effectiveness of pyramiding/stacking of disease resistance genes. The pyramided resistance genes from ICML 22 and 843B that were present in ICMB 99022 proved effective against eight of the nine pathogen isolates used in their study. Overexpression of a pearl millet cysteine protease inhibitor that exhibits potent antifungal activity against important phytopathogenic fungi (Joshi *et al.*, 1998) might be another option.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Traditional breeding has been for many years the main avenue for crop improvement in pearl millet, but is limited in that it only allows the exploitation of variation present in these species or in wild relatives with which they can be crossed. Recombinant DNA technology permits a more precise and predictable introduction of a broader array of traits than does traditional plant breeding.

Modern agricultural biotechnology, which involves the application of cellular and molecular techniques to transfer DNA that encodes a desired trait to food and feed crops, is proving to be a powerful complement to traditional methods to meet global food requirements. An important aspect of biotechnology is that it provides access to a broad array of traits that can help to meet this need for nutritionally improved cultivars (CRFSFS, 2004) and other desirable traits.

2. TRANSGENIC PEARL MILLET

2.1 Tissue Culture Amenability

The establishment of a reliable transformation protocol for pearl millet would form the basis for future genetic enhancement of this crop by complementing classical breeding programs for the benefit of India and sub-Saharan Africa. As a first step toward a routine transformation system, it is essential to establish a reliable and highly efficient regeneration system for selected pearl millet lines. An improved regeneration capacity for selected pearl millet lines would underpin the development of a reliable transformation system. *In vitro* culture of cereals shows strong genotype dependence, and production of the appropriate culture is generally limited to selected genotypes (Lambé *et al.*, 1999).

Procedures for the regeneration of pearl millet plants via somatic embryogenesis have been described for immature zygotic embryos (IZEs) (Vasil and Vasil, 1981; Lambé *et al.*, 1995; Oldach *et al.*, 2001; Goldman *et al.*, 2003; O'Kennedy *et al.*, 2004b), mature embryos (Botti and Vasil, 1983), immature inflorescences (Vasil and Vasil, 1981; Pinard and Chandrapalaiah, 1991; Pius *et al.*, 1993; Goldman *et al.*, 2003), shoot apices (Lambé *et al.*, 1999, 2000; Devi and Sticklen, 2002), and apical meristems (Goldman *et al.*, 2003). The addition of L-proline to the tissue culture induction medium resulted in a highly efficient embryogenic regeneration system for pearl millet, obtaining on average 80 regenerants per immature zygotic embryo explant (O'Kennedy *et al.*, 2004b). Shaved immature inflorescences provided a greatly increased surface area in contact with the culture medium for the generation of embryogenic tissues in comparison with immature inflorescence segments and even immature embryos (Goldman *et al.*, 2003).

2.2 Transformation and Selection Methodology

A transformation protocol was established using the herbicide resistance selectable marker gene, *bar*, and the particle inflow gun (PIG) (Girgi *et al.*, 2002). However, the transformation efficiency obtained was very low (0.02%) (Table 1). Using the same selectable marker gene, much higher transformation efficiency and far fewer escapes were achieved with shaved immature inflorescence cultures and the biolistic device from Bio-Rad (Goldman *et al.*, 2003). Subsequently, the *manA* (POSITECH, Syngenta) as positive selectable marker gene was investigated (O’Kennedy *et al.*, 2004a). The system employs the phosphomannose isomerase (PMI) expressing gene (*manA*) as a selectable marker and mannose, converted to mannose-6-phosphate by endogenous hexokinase, as selective agent (Joersbo *et al.*, 1999). The mannose positive selection system favors the regeneration and growth of the transgenic cells while the nontransgenic cells are starved but not killed. Therefore, untransformed tissue is separated from transgenic tissue by carbohydrate starvation of the untransformed cells. The use of *manA* selection limited the number of escapes

to less than 10%, whereas using the *bar* gene and selecting with 3–5 mg l⁻¹ bialaphos (the active ingredient of the herbicide) resulted in more than 90% nontransformed escapes (Girgi *et al.*, 2002). The *manA* selection system not only improved the transformation efficiency but also avoided the use of antibiotic or herbicide resistance genes as selectable markers in pearl millet transformation (O’Kennedy *et al.*, 2004a). To date, no *Agrobacterium*-mediated transformation of pearl millet has been reported.

Current transformation efficiencies are sufficient for testing of candidate genes, but a more efficient optimized system will be required for pearl millet transformation in high-throughput functional genomics projects.

2.3 Decreased Disease Susceptibility in Transgenic Pearl Millet

The most important applications of biotechnology for plant protection amongst the ICRISAT mandate crops, especially in Africa, include downy mildew resistance in pearl millet (Sharma and Ortiz, 2000).

^(e)Phosphinothricin acetyl transferase herbicide selectable marker gene

^(f)Phosphomannose isomerase positive selectable marker gene

^(g)Antifungal protein AFP from the ascomycete *Aspergillus giganteus*

^(h)Synthetic prawn antifungal protein encoding gene

The antimicrobial protein gene *afp* from the mold *Aspergillus giganteus* was introduced into two pearl millet genotypes by particle bombardment (Girgi *et al.*, 2006). Stable integration and expression of the *afp* gene was confirmed in two independent transgenic T₀ plants and their progeny using Southern blot and reverse transcription polymerase chain reaction analysis. *In vitro* infection of detached leaves and *in vivo* inoculation of whole plants with the basidiomycete *P. substriata*, the causal agent of rust disease, and the oomycete *S. graminicola*, causal agent of downy mildew, resulted in a significant reduction of disease symptoms in comparison to wild-type control plants. The disease resistance of pearl millet was increased by up to 90% when infected with two diverse, economically important pathogens. Disease resistance against *S. graminicola* was also obtained by expressing the puroindoline protein encoded by the synthetic prawn antifungal gene in the downy mildew susceptible genotype ICMP451 (Latha *et al.*, 2006). These are the first published reports of genetic engineering for resistance of pearl millet against infections by plant microbes.

Trichoderma atroviride is a well-known biological control agent, which can be used in combination with *Bacillus* spp. to combat *S. graminicola*, causal agent of downy mildew in pearl millet (Shetty and Kumar, 2000). Previous studies showed that a 78-kDa β -1,3-glucanase enzyme from *T. atroviride* exhibited potent antimicrobial activity to the oomycetous pathogen *Phytophthora* (Fogliano *et al.*, 2002). The *gluc78* gene (Donzelli *et al.*, 2001) from *T. atroviride*, which degrades glucan in the microbe's cell walls, was placed downstream of the potato proteinase inhibitor IIK wound inducible promoter followed by the rice *Act1* intron, and also downstream of the maize ubiquitin constitutive promoter and introduced into the genome of pearl millet (O'Kennedy *et al.*, unpublished results). Pathogenecity trials are currently underway.

2.4 Donor Gene: Isolation and Functional Analysis of Genes from Pearl Millet

All transgenic pearl millet studies undertaken to date have introduced genes from nonplant sources in order to confer tolerance to microbial pathogens

(see Section 2.3). While these genes have been shown to effectively confer tolerance to downy mildew and/or rust in transgenic pearl millet, they are of microbial origin. This may slow down the release of transgenic pearl millet lines due to the necessity of rigorous toxicity testing procedures, and also have implications for subsequent public acceptance of transgenic varieties. It would, therefore, be more suitable to isolate genes of interest (e.g., conferring abiotic and biotic stress tolerance) from existing pearl millet landraces and cultivars, and introduce these into stress susceptible pearl millet lines. Although very few examples of pearl millet gene isolation experiments exist in the literature, searches on National Centre for Biotechnology Information's (NCBI) Web site indicate that 3309 pearl millet sequences have been deposited in their database (www.ncbi.nlm.nih.gov). Although transformation with individual genes confers some degree of stress tolerance in transgenic plants, it is felt that regulated expression of more genes via overexpression of transcription factors or components of signaling pathways can lead to expression of a large number of relevant downstream genes, and sustained tolerance. This discussion will, therefore, focus on such examples of isolated pearl millet genes/gene fragments, and their potential application in future transgenic pearl millet projects.

One of the major objectives of pearl millet research is to introduce broad-spectrum disease tolerance into pearl millet lines. A study was undertaken to identify pearl millet genes that are differentially expressed in response to treatment with the fungal and bacterial pathogen elicitors, chitin and flagellin, respectively, and wounding (van den Berg *et al.*, 2004). Complementary DNA (cDNA) libraries were constructed from treated plants, and used in subsequent experiments to identify genes that are up- or down-regulated in response to treatment with the defense signaling molecules nitric oxide, salicylic acid, and methyl jasmonate, and also in response to rust treatment (Crampton and Berger, unpublished results). Substantial overlap was found to exist between jasmonate and salicylate signaling pathways, and genes involved in defense, signaling, oxidative burst, stress, basic/secondary metabolism, protein synthesis, and photosynthesis were identified. Identified candidate genes for pearl millet transgenic

studies that could confer broad-spectrum disease tolerance include a calcium binding EF hand protein and an ethylene responsive element binding protein (EREBP1). Calcium binding EF hand proteins are involved in detecting perturbations in cellular calcium levels following pathogen infection, and subsequent changes in metabolism and gene expression (Harmon *et al.*, 2000). Transcription factor EREBP1 mediates gene expression changes in response to various pathogens and defense elicitors (Euglem, 2005).

Mitogen-activated protein kinase (MAPK) cascades are major components downstream of receptors or sensors that transduce extracellular stimuli into intracellular responses, and are found in all eukaryotes analyzed to date (Innes, 2001). The basic assembly of a MAPK cascade is a three kinase module conserved in all eukaryotes. MAPK, the last kinase in the cascade, is activated by a kinase relay consisting of a MAPK kinase (MAPKK or MEK), which in turn is activated by a MAPKK kinase (MAPKKK or MEKK). MAPKs are activated by a variety of stress stimuli including wounding, temperature, drought, salinity osmolarity, ultraviolet (UV) irradiation, ozone, and reactive oxygen species. GenBank searches indicate that partial sequences exist for pearl millet MAP kinase kinase 1 mRNA (messenger RNA) (accession number AY147852), and a MEK1-like MAP kinase kinase mRNA (accession number AY147853), which are induced under salinity stress. Introduction of full-length sequences of these genes into pearl millet under the control of a saline-inducible promoter will potentially activate the MAPK cascade, which will in turn induce downstream genes involved in salinity tolerance.

Postflowering drought stress is one of the most common and serious environmental constraints of pearl millet production in sub-Saharan Africa and the Indian subcontinent (van Oosterom *et al.*, 1996). A number of drought responsive gene sequences exist in the GenBank (www.ncbi.nlm.nih), but of particular interest are a partial drought responsive element binding factor (DREB) sequence (accession number AY823566) and a complete pearl millet *DREB2A* gene sequence (accession number DQ227697). DREBs are transcription factors that induce a set of abiotic stress related genes, and impart stress endurance to plants. The DREB transcription factors are independent of

abscisic acid signaling, and can be dichotomized as DREB1 and DREB2, which are involved in two separate signal transduction pathways under low temperature and dehydration, respectively (Agarwal *et al.*, 2006). A number of transgenic plants have been made expressing DREB genes (as summarized in Agarwal *et al.*, 2006), and overexpression of a stress-inducible DREB transcription factor was found to activate the expression of many target genes having DRE elements in their promoters, and the resulting transgenic plants showed improved stress tolerance.

Many of the pearl millet sequences submitted to the GenBank represent partial mRNA sequences. It will, therefore, be necessary to isolate the coding sequence in its entirety before introducing the gene into pearl millet. Once isolated, functional analyses of pearl millet genes can be achieved by direct introduction into pearl millet and assessing the effect of their overexpression. Alternatively, RNA silencing of the gene of interest (Miki *et al.*, 2005) would enable researchers to study the effect of drastically down-regulating the gene, and determine its role in a particular stress response; namely, if the plant is highly susceptible to a stress following knockdown, then the expression of the gene plays an important role in the stress response. Stress-related pearl millet gene sequences will also provide a novel source of material for promoter mining studies. Genome walking (Rishi *et al.*, 2004) experiments upstream of the transcription start site will reveal regulatory sequences that could be a useful source of inducible promoters for transgenic studies.

2.5 Testing of the Activity and Stability of Inheritance of Transgenes, and Their Adverse Effects on Growth, Yield, and Quality

The concerns of consumers and regulatory authorities mean that transgenic crops are currently being subjected to detailed scrutiny to assess their safety for use in food. Random insertion of transgenes by the biolistic and *Agrobacterium*-mediated approaches has led to the suggestion that transgenes may have unpredicted effects on the expression of other endogenous genes, depending on their sites of insertion. Even an infrequent event could have serious consequences if it resulted in

the production of deleterious components or the loss of components that currently contribute to nutritional or processing quality. A key element of this comparative safety assessment is that a food or feed derived from a genetically modified (GM) crop is shown to be as safe as its conventionally bred counterpart. Application of the principle of substantial equivalence involves identifying the similarities and any differences between a product and its closest traditional counterpart and subjecting the differences to a rigorous safety assessment.

“Substantial equivalence” has recently been shown for transgenic wheat lines expressing the high molecular weight subunit transgenes assessing field performance (Shewry *et al.*, 2006), transcriptome of wheat grain in comparison with conventional breeding (Baudo *et al.*, 2006), and metabolomic studies of substantial equivalence of field-grown GM wheat (Baker *et al.*, 2006), which can only promote public acceptance of genetically produced food crops.

3. FUTURE ROAD MAP

3.1 Future Research Areas: Enhancement of Nutritional Quality

Bioavailable iron, vitamin A, and zinc are mainly provided in the human diet by animal food sources. In the developing world, where poorer individuals consume predominantly plant-based diets, deficiencies of these micronutrients are common and can occur in the same individual (Hess *et al.*, 2005). In the past decade, micronutrient malnutrition has been identified as a major underlying cause of numerous human health problems in developing countries (Toenneissen, 2002) with nutritional deficiency most acute amongst the poor. The magnitude of persistent deficiencies of micronutrient, iron and zinc, iodine and vitamins are particularly alarming among children, women at reproductive age, and pregnant and lactating women. Current efforts to combat micronutrient malnutrition in the developing world focus on providing vitamin and mineral supplements on fortifying foods during processing. With molecular markers, it is now possible to tag the genes responsible for the trait of interest, which then facilitate incorporating the genes into new breeding lines. Mutant cereal lines with

high β -carotene (provitamin A) content in the nonphotosynthetic edible tissues can be used in breeding; if such mutants do not exist, the carotenoid biosynthetic pathway can be introduced by genetic engineering. Paine *et al.* (2005) successfully introduced sufficiently high ($37 \mu\text{g g}^{-1}$) levels of β -carotene into the genome of rice. Based on a retinol equivalency ratio for β -carotene of 12:1, 50% of the children's recommended dietary allowance is delivered by 72 g of dry Golden Rice 2. This technology development can effectively be applied to other cereals, such as pearl millet.

Studies on the interaction between vitamin A and iron have produced quite compelling evidence that vitamin A deficiency decreases iron utilization, as well as clear evidence of the public health benefits of dual supplementation of iron and vitamin A to populations deficient in both nutrients so as to improve the impact of the iron on hemoglobin levels (Hess *et al.*, 2005). An interaction between vitamin A and zinc also appears to occur, but its public health importance remains unclear and will likely remain that way until a better measure of zinc status is developed (Hess *et al.*, 2005).

3.2 Addressing Risks and Concerns: Damage to Human Health and Environment

It is essential to reduce direct pollen-mediated gene flow from GM pearl millet to non-GM plants, as pearl millet is indigenous to Africa. In order to adhere to biosafety regulations and to minimize inadvertent introgression of transgenes into non-GM pearl millet varieties, the following strategies have potential to be applied to transgenic pearl millet. Firstly, the removal of antibiotic or herbicidal selectable marker genes that confer resistance to antibiotics or herbicides (Scutt *et al.*, 2002) and secondly the use of a positive selectable marker gene, such as *manA* (O'Kennedy *et al.*, 2004a), will be desirable. The latter should not confer any selective advantage to weedy subspecies if outcrossing was to occur. Thirdly, cytoplasmic-nuclear male sterility (CMS) can be used to severely restrict, but not eliminate, pollen-mediated gene flow. CMS has been well characterized in pearl millet and is routinely used for the production of hybrid seed (Andrews *et al.*,

1996). Gene flow through pollen could be restricted by CMS in fields where maintainer lines are sown for cross-pollination. However, it is likely that pollen from wild subspecies that transmits restorer genes would be present under some circumstances, and a male-fertile transgenic plant eventually would arise. Gene flow between wild subspecies and pearl millet has been documented (Renno *et al.*, 1997). Other strategies for transgene containment in addition to male sterility have been proposed (Daniell, 2002; Stewart *et al.*, 2003). These include maternal inheritance, linkage disequilibrium, gene use restriction technology, transgene mitigation, and apomixis. Gene use restriction technology includes the “terminator technology” for seed sterility and has been an unpopular approach. More empirical data for effectiveness of transgene containment are available for maternal inheritance and transgene mitigation. Maternal inheritance typically is achieved through chloroplast transformation. Chloroplast transformation has been repeatedly accomplished in tobacco (Daniell *et al.*, 2005) but has not yet been attempted in pearl millet. Chloroplast transformation most easily is carried out with chlorophyll-containing tissues. Therefore, chloroplast transformation may be more feasible using a shoot regeneration system for pearl millet such as that developed by Devi and Sticklen (2002) instead of the more commonly used embryogenic culture system, although recent progress indicates that plastids in embryogenic tissues can be transformed (Daniell *et al.*, 2005). Transgene mitigation and linkage disequilibrium (LD) are related in that transgene mitigation takes advantage of two closely linked genes that have a low probability of recombination (LD), one gene of which would reduce the competitiveness of weeds. Domestication traits, such as dwarf and nonshattering seed heads, are examples of traits selected for agricultural crops that would reduce the competitiveness of weeds (Gressel, 1999). Even though apomixis (asexual reproduction through seeds) occurs in wild relatives of pearl millet and has been introgressed into the crop species (Dujardin and Hanna, 1989c; Goel *et al.*, 2003), pollination of graminaceous apomicts is required for endosperm development. Therefore, male sterility accompanying apomixis still would require the interplanting of a pollinator as for CMS lines. In contrast to CMS, production

of recombinant embryos would be less likely. Furthermore, the existing apomictic pearl millet introgression lines have been developed at the tetraploid level (Dujardin and Hanna, 1989a, 1989c; Ozias-Akins *et al.*, 2003) and crosses with wild diploid relatives would yield rare and unfit triploids. Lastly, the necessity for transgene containment may vary depending upon the trait. The introduction of transgenes for nutritional quality improvement that confer no agronomical or competitive advantage to weedy species and non-GM varieties should not only be a safe technology but also would help to meet the acute need for nutritionally enhanced staple food crops in Africa.

3.3 Expected Technologies

Although no *Agrobacterium*-mediated transformation system yet exists for pearl millet, it is still worth exploring whether *Agrobacterium* transformation can be more efficient than particle bombardment in this species. *Agrobacterium* has become the standard for rice transformation (Hiei *et al.*, 1997). It also is now preferred for maize transformation (Zhao *et al.*, 2001; Frame *et al.*, 2002; Sidorov *et al.*, 2006) but remains relatively inefficient for sorghum transformation (Howe *et al.*, 2006). A distinct advantage of *Agrobacterium* transformation is the lower number of gene copies introduced into the transformed host genome compared with biolistic methods. Nevertheless, transfer DNA (T-DNA) insertions are not precise as once thought and plasmid backbone sequences beyond the T-DNA borders frequently are found in the transformed genome (Shou *et al.*, 2004).

The biolistic approach in combination with clean gene technologies or minimal transgene expression cassettes is a useful tool to produce a product that is free of antibiotic resistance genes in order to adhere to regulatory food safety requirements especially for a staple food crop indigenous to Africa. Minimal transgene cassettes (promoter-coding sequence-terminator sequence) were successfully introduced into the genome of pearl millet (O’Kennedy, unpublished results) in order to (1) eliminate backbone sequences containing repetitive sequences, which could lead to gene silencing and overload of non-sense DNA into the genome of a food crop, and (2) eliminate

antibiotic resistance marker genes (e.g., *Amp^R*), which are necessary for mass production of the genes of interest in *Escherichia coli* cells, but redundant for pearl millet transformation. The approach of introducing minimal transgene cassettes by biolistic transformation potentially enhances low copy number integration of transgenes, and minimizes transgene rearrangements and gene silencing as previously reported (Kohli *et al.*, 1998; Fu *et al.*, 2000). Vector backbones have the tendency to promote transgene rearrangements, since the vector backbone has been shown to provide a number of recombination hotspots, and the removal of these sequences would limit the influence of recombinogenic elements on the process of integration (Fu *et al.*, 2000).

3.4 IPR, Public Perceptions, Industrial Perspectives, and Political and Economic Consequences

In spite of substantial introduction of new pearl millet varieties in semi-arid sub-Saharan Africa during the recent decades (Monyo, 2002), inorganic fertilizers and improved water management are essential for large yield increases (Ahmed *et al.*, 2000). Government policies, transportation infrastructure, and market development of the target African countries and crops also need to be addressed for conventional and/or transformation-based crop cultivar improvement to significantly contribute to food supply.

New lines of millets containing transgenes will need to be tested at least as stringently as any other introduced or improved cultivars of these crops. A thorough assessment of their allergenic potential and the monitoring of any unintended effects on food composition will provide a solid basis for food safety assessment. The FAO/WHO have provided decision trees for a rigorous assessment and testing for GM foods (Halsberger, 2003), which would be applicable to transgenic pearl millet expressing the genes of interest. Furthermore, the phenotypes of transgenic pearl millet plants produced and the milling and processing qualities of the transgenic seed need to be assessed.

Finally, the gains in food production provided by the green revolution have reached their ceiling while the world population continues to rise

(Wisniewski *et al.*, 2002). A new green revolution will necessitate the application of recent advances in plant breeding, including new tissue culture techniques, marker-aided selection, mutagenesis, and genetic modification (Wisniewski *et al.*, 2002) to meet our increasing requirement for food, feed, fodder, and fuel, with cereal grains playing a pivotal role (Hoisington *et al.*, 1999). Whereas the affluent nations can afford to adopt elitist positions and pay more for food produced by the so called natural methods, the one billion chronically poor and hungry people of this world cannot (Wisniewski *et al.*, 2002). Therefore, despite the diverse and widespread potential for beneficial applications of transgenic products in agriculture, there remains a critical need to present these benefits to the general public in a real and understandable way that stimulates an unbiased and responsible public debate (Sharma *et al.*, 2002) and pro-GM government policies.

1. INTRODUCTION

Millets are one of the world's important food crops among cereals, primarily grown in arid and semi-arid regions of Asia and Africa. The various millets, designated as coarse cereals, are known to thrive well in the harsh climates such as high temperatures and low rainfall areas, where other crops fail to grow (Goldman *et al.*, 2003). Millets are nutritionally at par with other cereals and are the principal sources of energy, proteins, vitamins, and minerals. The projected food demand for 2025 warrants yields of millets to be increased from 2.5 to 4.5 t ha⁻¹ (Borlaug, 2002). These increases are expected to come from genetically improved varieties and transgenics exhibiting durable resistance to abiotic and biotic stresses using tertiary gene pools.

1.1 History, Origin, and Distribution

Finger millet, *Eleusine coracana* (L.) Gaertn., also known as African millet or *ragi*, has outstanding attributes as a subsistence food crop. *E. coracana* (L.) Gaertn. ssp. *coracana* belongs to a relatively small genus with 9 of its 11 species predominantly African in distribution (Phillips, 1972; Hilu and de Wet, 1976a). The crop was believed to have been domesticated in India from its weedy relative *E. indica* (L.) Gaertn. (Cobley, 1963; Vishnu, 1968). Others supported an origin in Africa from

E. coracana ssp. *africana* (Kennedy-O'Bryne, 1956; Mehra, 1963; Porteres, 1970; Hilu and de Wet, 1976b). However, Kennedy-O'Bryne (1956) and Jameson (1970) proposed independent origins for the crop in both Africa and India from subspecies *africana* and *E. indica*, respectively. Hilu and de Wet (1976a, b) and Hilu *et al.* (1978), based on biosystematic, ethnobotanic, and linguistic evidences, proposed the East African origin of *E. coracana* and its differentiation and domestication from the subspecies *africana*. Most probably the crop was later introduced into India via sea routes as early as the third millennium BC (Hilu *et al.*, 1979).

1.2 Botanical Description

The cultivated *E. coracana* is an erect, annual grass, growing to about 2–4 feet height with tillering-tufted stems. When mature, the stems are somewhat laterally flattened, bearing a whorl of 4–6 digitate, straight or slightly incurved spikes. The spikes are about 1/2 in. broad and 5–6 in. long; the numerous spikelets (about 70) are arranged alternately on the rachis. Each spikelet contains 4–7 seeds varying in diameter from 1 to 2 mm. The seeds are globose or somewhat flattened, smooth or rugose, and differ in color from dark reddish brown to nearly white.

Eleusine (L.) Gaertn. (Poaceae) is a small genus comprising nine species closely allied to *Acrachne*

and *Dactyloctenium* belonging to subtribe Eleusinae of the subfamily Chloridoideae (Phillips, 1972; Clayton and Renvoze, 1986). This genus is characterized by spikes of overlapping spikelets and an ornate grain enclosed by a free pericarp. The center of diversity for *Eleusine* is located in Ethiopia (East Africa) where eight of its species, namely, diploid annuals *E. indica* (L.) ($n = 9$), *E. multiflora* ($n = 8$), and diploid perennials *E. floccifolia* ($n = 9$), *E. intermedia* ($n = 9$), *E. jaegeri* ($n = 10$), *E. semisterilis*, as well as tetraploid perennial *E. kigeziensis* ($n = 19$), tetraploid annual *E. coracana* (L.) subsp. *africana* ($n = 18$), have been found. The remaining species, diploid annual *E. tristachya* ($n = 8$ or 9) is indigenous to the New World extending from South America to southwestern North America (Hilu, 1980); it also occurs in Africa as an occasional weed of limited distribution. The various species of *Eleusine* occupy diverse habitats ranging from open, dry places to understories of forests, and from sea level to high elevations. Some of the species, the cosmopolitan *E. indica* and its close relative *E. tristachya* grow as wild weeds beyond their indigenous ranges. Moreover, the genus includes the economically important cereal crop finger millet, *E. coracana* subsp. *coracana*, which is an annual tetraploid ($n = 18$) grown extensively in the semi-arid regions of Africa, India, and other countries. However, the diploid parents, genome composition, and evolutionary history of finger millet are incompletely understood (Hilu *et al.*, 1979).

Results from cytogenetic studies amply suggested that finger millet is an allotetraploid, derived directly from the wild tetraploid *E. coracana* subsp. *africana*, an annual weed occurring across much of Africa (Chennaveeraiah and Hiremath, 1974; Hiremath and Chennaveeraiah, 1982). Conspecificity of the *E. coracana* crop with, and its derivation from, its weedy relative subsp. *africana* is further supported by evidences from morphology, flavonoid chemistry, as well as analysis of chloroplast and ribosomal DNA (Hilu and De Wet, 1976a b; Hilu *et al.*, 1978; Hilu, 1988; Hilu and Johnson, 1991). That the *E. indica* ($n = 9$)—long suspected of being ancestral to *E. coracana* (Greenway, 1945)—is indeed the source of one of its genomes is now well established (Hilu, 1988; Hilu and Johnson, 1991; Hiremath and Salimath, 1992). However, the identity of the other parental diploid ($n = 9$) species remains unknown.

Among the polyploids are the cultivated *E. coracana* subsp. *coracana* and its putative wild ancestor, *E. coracana* subsp. *africana*. *E. coracana* was, thus, believed to be an allotetraploid derived from hybridization between *E. indica* and an unknown diploid. To evaluate this hypothesis, 16 isozyme loci coding for 9 enzymes were compared among 7 of the 9 *Eleusine* species. Substantial genetic variability was observed among the diploid species, ranging from $P = 0.563$, $A = 1.6$, $H = 0.208$ in *E. indica* to $P = 0.188$, $A = 1.2$, $H = 0.042$ in *E. jaegeri*. The diploids tended to be genetically distinct with values of Rogers' Similarity ranging from $S = 0.294$ (*E. jaegeri/floccifolia*) to $S = 0.794$ (*E. indica/tristachya*). Both the tetraploid subspecies *coracana* and *africana* disclosed fixed heterozygosity at several loci, confirming their allotetraploid status. These tetraploids invariably possessed *E. indica* marker alleles at all the loci, corroborating ancestry by this taxon. Genotypes of the non-*indica* ancestor, inferred separately for each tetraploid, differed substantially from all candidate diploids and also from each other. These data suggested that (1) none of the diploids investigated is likely to have been the non-*indica* ancestor of *E. coracana*, and (2) the non-*indica* diploid ancestor of the wild tetraploid may differ from that of the cultivated subsp. *coracana*. The latter conclusion, however, is inconsistent with the complete chromosomal homology observed between the two tetraploid subspecies, indicating the need for additional evidence bearing on their relationships (Charles *et al.*, 1994).

Deshpande and Ranjekar (1980) analyzed the genome of finger millet using DNA reassociation kinetics. The genome size has been estimated as 3.0×10^8 bp. The T_m values of cot 25 and cot 1 fractions were reported to be lowered by 10.8 and 12.8 °C, respectively, as compared to sonicated DNA indicating a base pair mismatch.

1.3 Economic Importance

Finger millet is grown in more than 4 million hectare worldwide and is the primary food source for millions of people in dryland regions of India and Central Africa. It occupies about 1.8 million hectares yielding about 2.34 million tons of grain with an average productivity of 1300 kg ha⁻¹ ([http://www.icrisat.org/Pearl Millet.htm](http://www.icrisat.org/Pearl%20Millet.htm)).

Finger millet is a typical dryland crop grown in semi-arid tropics of Africa and India. In East Africa, Ethiopia, and Somalia, it serves as the principal staple food of several tribes besides its use for malting and brewing. In India, grains are usually converted into flour and a variety of preparations, namely, cakes, puddings, porridge, etc., are made. A fermented drink is prepared from the grain in some parts of Maharashtra and in the Himalayan tracts in India. The grain is also malted and the flour of the malted grain is used as a nourishing food for infants and invalids, besides using it as a popular food supplement for diabetic patients. Its slow digestion leads to lesser increase in blood sugar levels, thereby acting as a safer food for diabetics.

Finger millet possesses excellent storage properties and is said to improve in quality as a result of storage; seeds of finger millet can be stored safely for several years without insect damage, and is a traditional component of farmers' risk avoidance strategies in the drought-prone areas (Sastri, 1989). The nutrient-rich grains are mainly used for making unleavened bread, while straw serves as a nutritious feed for the bovines. It is one of the richest sources of vitamins, proteins, and minerals such as calcium, while the iodine content is reported to be the highest among cereal grains. Finger millets have nutritional qualities superior to that of rice and is on a par with that of wheat. It is also a good source of essential amino acids like lysine and methionine. The malted grains of finger millet have a significantly higher saccharifying enzyme activity useful in brewing (Sastri, 1989).

1.4 *In Vitro* Plant Regeneration in Finger Millet

Development of a genotype-independent high-frequency regeneration system is an essential prerequisite for successful production of transgenic plants. Earlier reports on the morphogenetic response of different explants of finger millet are listed in Table 1.

Callus formation was induced from the cut end of the shoot tips of finger millet seedlings within 4–7 days. Among the 20 finger millet genotypes tested for their efficiency of callus induction, PGEC-2, showed the highest frequency (99%) of callus initiation on Murashige and Skoog (MS) medium supplemented with 2,4-D.

The calli were differentiated into embryogenic and nonembryogenic sectors within 10–12 days, and the frequency of embryogenesis, in PGEC-2, approximated to 90%. Embryogenic sectors of the calli were compact, nodular, and creamy-yellow, while nonembryogenic regions were white and friable. Embryogenic regions were subcultured on the callusing medium for 2 weeks for proliferation of the embryoids. These embryoids were later regenerated into plants with well-developed roots on the MS basal medium supplemented with 6-benzylaminopurine (BAP) (1.0 mg l^{-1}) and kinetin (0.5 mg l^{-1}). From each embryogenic callus (1–2 mm) more than 100 plantlets were regenerated. Thus, from a single shoot-tip explant, a maximum of >4000 plantlets could be established within 75 days in the glasshouse (Madhavi *et al.*, 2005).

1.5 Limitations of Traditional Breeding

That cultivated *E. coaracana* subsp. *coaracana* is a polyploidy is also evidenced by duplicate loci for various morphological characters. The inheritance of numerous qualitative traits, such as purple pigmentation, grain color, sterility, pericarp color, elongation of earhead (spike), glume length, earhead (spike) shape, etc., were investigated; whereas, for characters important in breeding, very limited genetic studies have been made (Richaria, 1957).

In the past, mass and pure line selections were used to isolate improved strains from introductions and mixed local varieties. Hybridization followed by pedigree, bulk, and backcross methods have been used to improve grain yield, maturity, lodging resistance, disease resistance, grain quality, etc. (Chavan and Shendge, 1957; Poehlman and Borthakur, 1969).

Sixteen fungal, three viral, and at least one bacterial pathogen have been reported to infect finger millet. Leaf blast disease caused by the fungus *Pyricularia grisea* has been identified as the most devastating disease in finger millet affecting its production in South Asia and Africa (Ramakrishnan, 1963). *P. grisea* is pathogenic to more than 50 graminaceous hosts including common crops such as rice, finger millet, foxtail millet, and wheat. It causes complete harvest loss when it occurs prior to grain formation (Ekwanu, 1991). Various finger millet landraces were found

Table 1 Morphogenic response in finger millet

Explant	Callusing medium	Regeneration medium	References

to be highly susceptible to blast disease resulting in heavy yield losses. In India, blast disease caused annual yield losses ranging from 28% to 50% in the endemic areas (Sastri, 1989). Adoption of conventional methods of breeding met with limited success for developing durable resistance to leaf blast disease (Coca *et al.*, 2004).

1.6 Rationale for Production of Transgenics

Genetic transformation is extensively used as a method of choice for transferring desired genes into commercial crop cultivars for enhancing various agronomic attributes. Developments in gene transfer methods have made it feasible to rapidly introduce exotic stress tolerance genes into diverse crop plants. There are several successful examples

of transgenics showing enhanced tolerance to various biotic and abiotic stress factors. Because of the nonavailability of desired resistance genes in the primary and secondary gene pools of *Elusine* for developing durable resistance to leaf blast disease and salt tolerance, genetic engineering approaches deploying novel resistance genes from tertiary gene pools have been adopted.

2. TRANSGENICS DEVELOPED IN FINGER MILLET

Development of reproducible gene transfer systems is essential for the introduction of candidate exotic genes into the genomes of different crop plants for enhancing various agronomic traits. *Agrobacterium*-mediated and

microprojectile bombardment methods are widely employed to produce various transgenic plants in diverse crops. Most of the major cereal crops such as rice, wheat, maize, etc., have been successfully transformed using these methods.

Transformation of different millets has so far lagged behind in comparison to other cereals. However, limited attempts have been made in finger millet for the establishment of gene transfer system. Gupta *et al.* (2001) used different plasmid constructs containing *gusA* gene driven by five promoters, namely, Actin1, ubiquitin 1, RbcS, cauliflower mosaic virus (CaMV) 35S, and ppcA-L-Ft, to assess the efficacy of these promoters based on the transient β -glucuronidase activity. These constructs were bombarded into calli derived from mature embryo, leaf lamina, and leaf sheath of finger millet using biolistic TMPDS-1000/He particle delivery system. They reported the highest transient expression of *gusA* gene driven by the maize ubiquitin promoter when compared to other promoters, and concluded that ubiquitin 1 is the most efficient promoter. Shiva Kumar *et al.* (2005) reported standardization of transformation protocols in finger millet employing particle bombardment and *Agrobacterium* methods using *gusA* as a reporter gene.

2.1 Plasmids Used for Production of Transgenics by Particle-Inflow-Gun Method

Plasmid vectors, pPur, pBar, pPin, and pPcSrp carrying *gusA*, *bar*, *pin*, and *PcSrp* genes, driven by CaMV 35S, rice actin, and *Porteresia coarctata* (*Pccp*) promoters along with *nos* terminator, were used for production of finger millet transformants. For optimization of transformation conditions using particle-inflow-gun method, plasmid constructs containing *gusA* and *bar* genes were employed. Embryogenic calli, derived from shoot-tip cultures, were used as target tissue for production of transgenic plants. The calli were bombarded with 1.1 μ m size tungsten particles using the optimized parameters, namely, 15 kg cm⁻² helium gas pressure, 7 cm target distance, 4 h of pre- and postbombardment osmotic treatments with 0.2 M equimolar concentration of sorbital and mannitol (Madhavi *et al.*, 2005).

2.2 Development of Blast-Resistant and Herbicide-Tolerant Transgenic Plants

For production of leaf blast-resistant and herbicide-tolerant finger millet, plasmids carrying *pin* gene and *bar* gene were introduced into the genome of finger millet employing particle-inflow-gun mediated transformation. The *pin* gene was chemically synthesized based on prawn antimicrobial peptide using two oligos with *Bam*HI and *Sac*I restriction enzyme sites (Madhavi *et al.*, 2005). The synthetic gene encoded a 38 amino acid antifungal peptide that was designated as PIN. The *pin* coding sequence was cloned between CaMV 35S promoter and *nos* terminator at *Bam*HI and *Sac*I sites of pPur after excising the *gusA* sequence, and was used for the production of blast-resistant finger millet plants.

Embryogenic calli, co-bombarded with pPin 35S and pBar 35S constructs, were subjected to phosphinothricin (PPT) selection, ranging from 5 to 12 mg l⁻¹ in a sequential manner, using a four-step-selection strategy for selecting stable transformants. About 1.9% of the bombarded calli could survive four stages of selection with PPT. The PPT-resistant calli were then transferred to the regeneration medium containing 1.0 mg l⁻¹ BAP and 0.5 mg l⁻¹ kinetin for plant regeneration. Regenerants with well-developed root system were transferred to the glass house and were grown to maturity. Most of the primary transformants were healthy and fertile with normal seed set.

The primary transformants (T₀) obtained with *bar* and *pin* genes were identified based on herbicide Basta test, polymerase chain reaction (PCR), Southern blot and Northern blot analyses. The various putative transformants when tested with Basta showed different levels of tolerance to the herbicide. The primary transgenic plants, subjected to PCR, revealed expected amplification products corresponding to the transgenes. Southern analysis, using enzymes with unique sites in the plasmid, showed 1–3 hybridizing bands of higher molecular weight than the plasmid size; it also disclosed 1–10 copies of transgenes with single to multiple integrations in the genomes of transgenic plants. An approximate 30% of the transformants showed the presence of single copies of the introduced transgenes. About 50% of transformants, in general, showed silencing of transgenes as evidenced by Northern blot analysis. Most of these

Figure 1 Transgenic finger millet plants expressing *pin* gene showing blast resistance

transformants were found positive for both *bar* and *pin* genes, confirming stable integration of transgenes into the genome of finger millet.

Three T_1 progenies of finger millet, expressing *pin* and *bar*, were subjected to fungal bioassays and herbicide Basta test to analyze the inheritance mode of introduced transgenes. When T_1 transgenics were scored on a scale of 0–9 for resistance/susceptibility reaction against *P. grisea*, the transgenic plants expressing *pin* displayed high-level resistance to the leaf blast disease (Figure ??). The fungus caused 0.1–0.5-mm lesions on resistant transgenics compared to 5–20-mm lesions observed on susceptible plants. Different T_1 progenies segregated into distinct resistant and susceptible phenotypes conforming to the monogenic ratio. The herbicide Basta test on transgenics also disclosed a clear segregation of 3 tolerant:1 susceptible plants (Madhavi *et al.*, 2005).

2.3 Production of Marker-Free and Salinity-Tolerant Finger Millet

Transgenic finger millet lines, tolerant to NaCl stress were produced by transferring a complementary DNA (cDNA) clone, designated as *PcSrp*, isolated from the cDNA library of salt stressed roots of *P. coarctata*, a salt-tolerant wild grass (Mahalakshmi *et al.*, 2006a). The *PcSrp* gene was cloned downstream to the actin promoter and the expression unit was introduced into calli of finger millet through the particle-inflow-gun method. For selection of transformed calli, 250 mM NaCl was used as a selection agent; selected NaCl-tolerant calli were then regenerated on the

medium containing BAP (1.0 mg l^{-1}), kinetin (0.5 mg l^{-1}), and NaCl (250 mM). Regenerated plants were subjected to NaCl stress and grown to maturity in the glass house. Southern blot analysis of transgenic plants revealed the presence of *PcSrp* gene in the genome of finger millet, and its expression was authenticated by Northern analysis. When T_1 transgenic plants were subjected to 250 mM NaCl salt stress, they segregated into 3 resistant:1 susceptible plants conforming to monogenic ratio. Tolerance of T_1 transformants to salt stress was assessed by subjecting 3-week-old $1T_1$ plants to 250 mM NaCl salt stress up to maturity. Transgenic plants under salt stress showed marked increases in root length, shoot length, and seedling fresh weight as compared to untransformed control plants, which failed to survive. The seed yield of $1T_1$ plants, subjected to 250 mM NaCl stress, ranged between 1.11 and 5.57 g/plant with a mean seed yield of 3.10 g/plant. On the other hand, under unstressed conditions, transgenic plants produced seed yield in the range of 7.73–14.4 g/plant, while in the untransformed plants the seed yield ranged between 15.44 and 29.48 g/plant (Mahalakshmi *et al.*, 2006a). These results amply suggest that use of a salt-inducible, root-specific promoter might obviate the energy drain caused by the constitutive expression of *PcSrp* in transgenic plants.

Under 250 mM NaCl stress, the transgenic plants accumulated higher amount of Na^+ ions in the roots compared to the roots of untransformed plants. On the contrary, the Na^+ ion content was higher in the shoots of untransformed plants compared to the shoots of transgenic plants. However, the untransformed control plants grown

under unstressed conditions accumulated lower Na^+ ions in the roots and shoots when compared to the stressed transgenic and control plants (Mahalakshmi *et al.*, 2006a). The K^+ ion content was higher in the roots of transgenic plants when compared to the roots of untransformed plants. Whereas, shoots of untransformed plants accumulated higher K^+ ion content than the shoots of transgenic plants. On the other hand, the roots of untransformed plants, grown under unstressed conditions, showed lesser K^+ ion content compared to the shoots. An overview of ion profiles amply demonstrates the unequivocal role of *Pcsrp* in bestowing salinity tolerance, by maintaining ion homeostasis, at the whole plant level (Mahalakshmi *et al.*, 2006a).

2.4 Evaluation of *Porteresia coarctata* Promoter in Finger Millet

Employing the *Prosearch* tool developed by us for identification of plant promoters, a promoter sequence, *Pccp*, containing 633 bp has been identified from the genomic sequences of *P. coarctata*, and the same was cloned upstream to *gusA* having *nos* terminator downstream. Using the particle-inflow-gun method, the fusion construct was introduced into callus and various other tissues of finger millet. The transformed tissues/plants showed transient and stable expression of *gusA* gene, confirming the predicted sequence (*Pccp*) of *P. coarctata* as a constitutive promoter (Mahalakshmi *et al.*, 2006b).

3. FUTURE ROAD MAP

Reproducible protocols have been optimized in finger millet for high-frequency *in vitro* plant regeneration as well as genotype-independent genetic transformation system using the particle-inflow-gun method. Employing these protocols, a synthetic antifungal *pin* gene was successfully introduced into finger millet. Stable transgenics, expressing puroindoline (PIN) protein, exhibited high-level resistance to the leaf blast disease. These transgenic lines, endowed with the exotic *pin* gene, appear promising as a novel genetic resource in conventional crossbreeding, besides their use for direct commercial cultivation in areas endemic to blast disease.

The novel *PcSrp* gene cloned from *P. coarctata*, upon introduction into the finger millet, imparted marked tolerance to salt stress at the whole plant level. The marker-free, prototype transgenic finger millet, fortified with *PcSrp*, might serve as a key parent in improving the salinity tolerance of elite finger millet cultivars.

Furthermore, the standardized plant regeneration and transformation protocols offer enormous scope for enhancing various agronomic attributes, such as disease and insect resistance, early maturity, lodging resistance, high harvest index, improved seed quality, etc., of finger millet by deploying desired genes isolated from diverse gene pools. Development of efficient gene transfer protocols using *Agrobacterium* should be given high priority, as this method facilitates single copy transgene integrations, which minimize gene silencing effects in subsequent generations as opposed to the particle-inflow-gun method.

Cool-Season Forage Grasses

Zeng-Yu Wang¹ and Toshihiko Yamada²

1. INTRODUCTION

1.1 History, Origin, and Distribution

Although the grass family is very large, relatively few species have been developed as forage crops, and even fewer species have been genetically transformed. Cool-season grasses make most of their growth under cool environment and serve as the primary forage for ruminant animals in temperate regions of the world. Cool-season grass species in which transgenic plants have been developed include: tall fescue (*Festuca arundinacea* Schreb.), perennial ryegrass (*Lolium perenne* L.), Italian ryegrass (*Lolium multiflorum* Lam.), orchardgrass (*Dactylis glomerata* L.), Kentucky bluegrass (*Poa pratensis* L.), and Russian wildrye (*Psathyrostachys juncea* (Fisch.) Nevski) (Wang and Ge, 2006). This chapter focuses on these forage-type grass species.

Tall fescue is indigenous to Europe, also naturally occurring on the Baltic coasts throughout the Caucasus, in western Siberia and extending into China (Jauhar, 1993). Tall fescue introductions have been made into North and South America, Australia, New Zealand, Japan, and South and East Asia (Barnes, 1990). It was introduced into the United States from Europe in the early 1800s. It is widely grown in southern Europe and is the predominant cool-season perennial grass species in the United States (Sleper and West, 1996; Stadelmann *et al.*, 1999).

Perennial and Italian ryegrasses are indigenous to parts of Europe, Asia, and North Africa (Jauhar, 1993; Jung *et al.*, 1996). The first records of cultivated use of perennial ryegrass came from England in about 1677, and Italian ryegrass was grown in Italy under irrigation as a cut forage crop in the 13th century (Jung *et al.*, 1996). The spread of ryegrasses is closely associated with the development of livestock farming. Ryegrasses are widely distributed throughout the temperate zones and are extensively used in Europe, Australia, New Zealand, North America, and Japan (Jung *et al.*, 1996).

Orchardgrass is native to Europe, North Africa, and parts of Asia. This species was introduced into the United States probably in the 1750s, and in 1763 seed was shipped to the United Kingdom from Virginia (Christie and McElroy, 1995). Orchardgrass was first described in North America from plants found growing in an orchard in Virginia. Its British common name, “cocksfoot” refers to the characteristic shape of the panicle (Van Santen and Sleper, 1996). Orchardgrass is perennial forage widely adapted on all continents including the Kerguelen and Crozet Islands of Antarctica (Van Santen and Sleper, 1996).

Kentucky bluegrass is native to Europe, northern Asia, and the mountains of Algeria and Morocco. It is now ubiquitous in permanent pastures in humid temperate regions of the United States, occurring in every state and extending to Canada (Balasko *et al.*, 1995).

Russian wildrye is indigenous to the Eurasian interior. The first recorded introduction into the United States was made in 1927 by United States Department of Agriculture (USDA) (Asay and Jensen, 1996). In North America, it has been seeded most often on arid and semi-arid rangelands of the Northern Great Plains and intermountain regions. Russian wildrye occurs naturally from Iran northward to the lower Volga River and lower Don River regions of Russia in the north, eastward into western Siberia and across Asia to Mongolia and northern China (Asay and Jensen, 1996).

1.2 Taxonomy, Genome Size, and Cytological Features

Festuca is a diverse and widely adapted genus which contains over 80 species, of which approximately 20 exist in the United States (Barnes, 1990). Tall fescue (*F. arundinacea* Schreb.) is the most important forage species worldwide of the *Festuca* genus (Sleper and West, 1996). Tall fescue is a polyploid ($2n = 6x = 42$), wind-pollinated species with a high degree of self-incompatibility. Its genome size is approximately 6×10^3 Mbp (mega base pair) (Seal, 1983). Tall fescue is an outcrossing hexaploid that contains three genomes (P, G1, and G2). The P ($2x$) genome is from a diploid species, meadow fescue (*F. pratensis*), while the G1 and G2 ($4x$) genomes are from a tetraploid species, *F. arundinacea* var. "glauescens" (Sleper, 1985).

Lolium L. is a small genus which includes only eight diploid ($2n = 2x = 14$) species (Terrell, 1966). The commercially most important ryegrasses in cool temperate climates throughout the world are perennial ryegrass (*L. perenne* L.) and Italian or annual ryegrass (*L. multiflorum* Lam.). Both species are outcrossing with genome sizes of about 1.7×10^3 Mbp for perennial ryegrass (Bert *et al.*, 1999) and 2.0×10^3 Mbp for Italian ryegrass (Hutchinson *et al.*, 1979; Inoue *et al.*, 2004).

The genus *Dactylis* is monospecific genus, *D. glomerata* L., divides into many subspecies with ploidy level ranging from diploid ($2n = 2x = 14$) to hexaploid ($2n = 6x = 42$). Tetraploids arose from diploids by chromosome doubling. Cultivated orchardgrass belongs to the subspecies *glomerata*, which is a tetrasomic polyploid with $4x$ chromosomes (Van Santen and Sleper, 1996). The genome size of the tetraploid populations varies

from 3.2×10^3 to 4.3×10^3 Mbp (Creber *et al.*, 1994).

Kentucky bluegrass (*P. pratensis* L.) is a facultative apomictic species. The form of apomixis in Kentucky bluegrass is pseudogamous apospory, although it is also capable of reproducing sexually to varying degrees. A complex series of polyploidy and aneuploidy exists in Kentucky bluegrass. Within the species, chromosome numbers range between 24 and 124 with skewed distributional modes in the 56–59, 63–70, and 84–91 chromosome-number classes (Wedin and Huff, 1996).

Psathyrostachys contains about 10 diploid species including diploids, autotetraploids, and autohexaploids, and they all have the Ns genome (Vogel *et al.*, 1999). Russian wildrye is the only species of *Psathyrostachys* that has proven to be an important forage grass. In its native habitat, it is widely distributed on open slopes and steppes from the Middle East and Russia across central Asia to northern China. The genome size of Russian wildrye is estimated to be 7.5×10^3 Mbp (Vogel *et al.*, 1999). It is typically a cross-pollinated diploid ($2n = 2x = 14$); however, autotetraploid ($2n = 4x = 28$) forms have been artificially induced, and such types may occur in nature (Asay, 1995).

1.3 Economic Importance

Cool-season grasses have played an important role in providing pasture and hay for the livestock industry and are important in soil conservation and environmental protection. Besides being used as forage, some of the grasses, such as turf-type tall fescue, ryegrasses, and Kentucky bluegrass have been widely used for amenity purpose on lawns, parks, sports fields, golf courses, and roadsides.

Tall fescue is a leafy, course-textured, vigorous perennial bunchgrass that reproduces vegetatively through tillering and by seed. It forms the basis for beef cow-calf production in the east-central and southeast United States, supporting over 8.5 million beef cows on 12–14 million hectares of planted areas, and is used for sheep and horse production (Buckner *et al.*, 1979; Hoveland, 1993; Sleper and West, 1996). Its widespread use in the United States can be attributed to a long list of desirable agronomic characteristics, including high yields of herbage, excellent persistence, adaptation

to a wide range of soil conditions, compatibility with various management practices, long grazing season, and low incidence of pest problems (Hanson, 1979; Sleper and West, 1996).

Perennial ryegrass is a palatable, persistent grass of high tillering density that shows resistance to treading and good response to high nitrogen application. In New Zealand, perennial ryegrass is grown on 7 million hectares providing high quality forage to support 60 million sheep and cattle. Perennial ryegrass is—with an estimated 55 million kilograms of seed consumed annually—the main grass species in the European Union (EU) (Spangenberg *et al.*, 1998a).

Italian ryegrass is an annual or biennial highly palatable nutritious grass that shows a rapid establishment from seed, good production in the seeding year, and rapid recovery after defoliation (Jauhar, 1993). Italian ryegrass represents—with an estimated 36 million kilograms of seed—27% of the yearly grass seed consumption in the EU (Spangenberg *et al.*, 1998a). Perennial and Italian ryegrasses form the basis of most pastures for grazing and silage in New Zealand, Australia, and Europe. They are also widely grown in grasslands in the United States and Japan.

Orchardgrass is one of the most important forage grasses in Japan, it is especially adapted in the cooler climates such as the island of Hokkaido (Van Santen and Sleper, 1996). Orchardgrass is the second most commonly sown grass species contributing to a maximum of 10% to pasture production in New Zealand (Van Santen and Sleper, 1996). In the northeast and north-central United States, it is one of the major grass species for pasture (Christie and McElroy, 1995).

Kentucky bluegrass spreads by rhizomes to form sod. Its rhizomatous growth habit makes heavy grazing or frequent cutting are not as detrimental to its sod formation as they are for more upright species (Wedin and Huff, 1996). Kentucky bluegrass is used for grazing on >15 million hectares of pastures throughout the northeastern and north-central United States and substantial areas of Europe and Canada (Eaton *et al.*, 2004).

Although Russian wildrye was introduced into North America in 1926, its potential in range improvement was not fully recognized until the 1950s. It since became an important forage grass on semi-arid rangelands of the intermountain West and Northern Great Plains. Russian wildrye is

exceptionally cold and drought tolerant (Asay and Jensen, 1996). The species provides valuable pasture that is often used to complement native rangeland during the late summer and fall when nutritive quality of most forages is relatively low (Asay, 1991).

1.4 Traditional Breeding: Objectives, Strategies, and Achievements

Breeding for improved forage grasses in North America began in earnest in the 1930s and 1940s. Compared to centuries of human involvement in domestication and selection in maize and other cereal crops, forage grass breeding is a relatively recent development. Many of the first grass cultivars widely used in the United States, such as “Kentucky-31” tall fescue, “Linn” perennial ryegrass, and “Merion” Kentucky bluegrass, were ecotypes subjected to little or no selective breeding for specific traits (Wang *et al.*, 2001a).

The release of new cultivars has tremendous impact on the adoption and expansion of grasses. For example, tall fescue grew on approximately 16 000 ha in 1940 in the United States, with the release of the “Kentucky-31” and “Alta” cultivars during the early 1940s by the Kentucky and Oregon Agricultural Experiment Stations, by 1973 it had become the predominant cool-season perennial grass occupying 12–14 million hectares (Buckner *et al.*, 1979; Sleper and Buckner, 1995).

Cultivars have been developed with documented improvement in traits such as forage quality (Vogel *et al.*, 1991) and seedling vigor (Asay *et al.*, 1985). For some traits, improvement has been inconsistent or slow, particularly with regard to forage yield. It was estimated that the average rate of genetic gain for yield was 13.5% per decade for several grain crops compared to 4% per decade for forage yield of several grasses and legumes (Humphreys, 1997). Several reasons have been suggested for such disparity, including the genomic complexity (e.g., polyploidy, outcrossing) typical of forage grasses, and insufficient breeding efforts devoted to improving forage yield of a given species (Casler *et al.*, 2000).

Persistence, a combination of several traits, such as drought, heat, and cold tolerance, is an important target for grass cultivar improvement. Similarly, improving forage quality, often via

selection for increased digestibility, is a critical objective in many forage grass breeding programs. It has been shown that increased digestibility can lead to substantial improvements in animal gains per hectare (Casler, 2001).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Genetic improvement of cool-season grasses by conventional plant breeding is slow since many of these species are predominantly, if not completely, allogamous wind-pollinated grasses and generally self-sterile (Kasperbauer, 1990; Jauhar, 1993; Spangenberg *et al.*, 1998b). These features represent a great challenge to the breeder because these plants are usually heterozygous, and self-incompatibility limits inbreeding to concentrate desired genes for use in rapid development of new cultivars (Kaul, 1990). Although many improved forage varieties have been developed through conventional breeding efforts, progress in improving particular traits has slowed (Ha *et al.*, 1992). Transgenic approaches are expected to accelerate or complement conventional breeding approaches, since they offer the opportunity to generate novel genetic variations that is either absent or has very low heritability.

2. DEVELOPMENT OF TRANSGENIC COOL-SEASON FORAGE GRASSES

2.1 Donor Genes, Promoters, and Selectable Markers

Much of the reported transformation work on cool-season forage grasses has been on method development using selectable marker genes and reporter genes (Table 1). The selectable marker genes used are: hygromycin phosphotransferase gene (*hph*) from *Escherichia coli*, phosphinothricin acetyltransferase gene (*bar*) from *Streptomyces hygroscopicus*, and neomycin phosphotransferase II gene (*nptII*) of transposon Tn5 (Table 1). The reporter genes are β -glucuronidase gene (*gusA*) from *E. coli* and green fluorescent protein gene (*mgfp*) from *Aequorea victoria*. For *Agrobacterium*-mediated transformation, the *gusA* reporter gene needs to have an intron (e.g., a

catalase intron) inside the coding sequence to ensure that expression of glucuronidase activity is derived from eukaryotic cells, not from expression by residual *A. tumefaciens* cells (Wang and Ge, 2005a, b).

The promoters used to construct the chimeric genes are: cauliflower mosaic virus (CaMV) 35S promoter, rice actin promoter, maize ubiquitin promoter, or tissue-specific promoters. The terminators used are the CaMV 35S terminator or the *nos* terminator from *Agrobacterium*.

Overexpression of heterologous genes is a straight forward approach for trait improvement. The target genes are often from unrelated species (Table 1). For example, to improve protein quality of forage grass for ruminant nutrition, the sunflower seed albumin 8 (*SFA8*) transgenes were constructed under the control of constitutive (CaMV 35S) and light-regulated (wheat cab) promoters (Wang *et al.*, 2001b). The transgenes were introduced into tall fescue and led to the accumulation of sulfur-rich SFA8 protein rich in sulfur-containing amino acids (methionine and cysteine) (Wang *et al.*, 2001b). To improve cold tolerance of perennial ryegrass, two fructan biosynthetic genes from wheat, *wft1* and *wft2*, which encode sucrose-fructan 6-fructosyltransferase (6-SFT) and sucrose-sucrose 1-fructosyltransferase (1-SST), respectively, were introduced into perennial ryegrass under the control of CaMV 35S promoter (Hisano *et al.*, 2004).

For down-regulation of endogenous genes, the target gene is normally isolated from a species and transferred back to the same species or closely related species. To improve forage digestibility by down-regulation of lignin biosynthesis, genes encoding two key enzymes involved in lignin biosynthesis, cinnamyl alcohol dehydrogenase (CAD), and caffeic acid *O*-methyltransferase (COMT), were cloned from tall fescue (Chen *et al.*, 2002). Transgenic tall fescue plants were produced using antisense and sense CAD and COMT gene constructs under the control of maize ubiquitin promoter. Severely reduced mRNA levels and significantly decreased enzymatic activities were found in some transgenic lines. These transgenic tall fescue plants had reduced lignin content, altered lignin composition, and increased *in vitro* dry matter digestibility (Chen *et al.*, 2003, 2004). In order to develop hypo-allergic grasses to reduce

hayfever and seasonal allergic asthma caused by grass pollen, genes encoding major pollen allergenic proteins, Lol p1 and Lol p2, were cloned from perennial ryegrass. The antisense *Lol p1* and *Lol p2* transgene under the control of a pollen-specific promoter were introduced into perennial and Italian ryegrasses (Petrovska *et al.*, 2004). The accumulation levels of Lol p1 and Lol p2 allergens in pollen were reduced in the transgenic ryegrass plants (Petrovska *et al.*, 2004).

2.2 Methods Employed for Transformation

Transgenic cool-season grass plants were first obtained by direct gene transfer to protoplasts (Horn *et al.*, 1988; Wang *et al.*, 1992). Because protoplast culture and transformation are very delicate systems to work with, in recent years biolistic transformation and *Agrobacterium*-mediated transformation have become the main methods for producing transgenic grasses.

As shown in Table 1, most of the protoplast works were done in the 1990s. Recovery of transgenic plants from protoplasts was reported for orchardgrass (Horn *et al.*, 1988), tall fescue (Ha *et al.*, 1992; Wang *et al.*, 1992; Dalton *et al.*, 1995; Kuai *et al.*, 1999), Italian ryegrass (Wang *et al.*, 1997), and perennial ryegrass (Wang *et al.*, 1997).

Biolistics or microprojectile bombardment employs high-velocity gold or tungsten particles to deliver DNA into living cells for stable transformation (Sanford, 1988; Christou, 1992). Because biolistic transformation is a physical process that involves only one biological system, it is a fairly reproducible procedure that can be easily adapted from one laboratory to another laboratory. Transgenic forage plants have been obtained by microprojectile bombardment of embryogenic cells in tall fescue (Spangenberg *et al.*, 1995a; Cho *et al.*, 2000; Wang *et al.*, 2001b, 2003a; Chen *et al.*, 2003, 2004), perennial ryegrass (Spangenberg *et al.*, 1995b; Dalton *et al.*, 1999; Altpeter *et al.*, 2000; Xu *et al.*, 2001; Petrovska *et al.*, 2004; Chen *et al.*, 2005), Italian ryegrass (Ye *et al.*, 1997, 2001; Dalton *et al.*, 1999; Li *et al.*, 2004; Petrovska *et al.*, 2004), orchardgrass (Denchev *et al.*, 1997; Cho *et al.*, 2001), Kentucky bluegrass (Ha *et al.*, 2001; Gao *et al.*, 2006), and Russian wildrye (Wang *et al.*, 2004a) (Table 1).

Agrobacterium-mediated transformation has the advantage of allowing for low copy number integration of the transgenes into the plant genome. In recent years, significant progress has been made in developing transformation protocols using *Agrobacterium tumefaciens* as a vector. Transgenics have been obtained by *Agrobacterium*-mediated transformation in tall fescue (Dong and Qu, 2005; Wang and Ge, 2005a), perennial ryegrass (Altpeter *et al.*, 2004; Wu *et al.*, 2005; Bajaj *et al.*, 2006; Sato and Takamizo, 2006), Italian ryegrass (Bettany *et al.*, 2003), and orchardgrass (Lee *et al.*, 2006).

2.3 Selection of Transformed Tissue

The establishment of efficient selection schemes by applying suitable selection pressure for an appropriate length of time is one of the critical aspects of successfully generating transgenic grasses. Because many grasses have high endogenous tolerance to antibiotics, particularly kanamycin, most of the reports in forage grass transformation used *hph* or *bar* as selectable marker gene and hygromycin or phosphinothricin (PPT) as selection agent (Table 1).

The stable integration and expression of a chimeric *hph* gene result in the ability to phosphorylate hygromycin, thus rendering the transformed plant cells resistant to concentrations of this antibiotic, which are lethal to untransformed cells. The expression of chimeric *bar* gene in transfected cells results in the acetylation of PPT and thus renders plant cells resistant to this herbicide. The concentrations of hygromycin and PPT used for selection varied with the species and the selection system used. For example, hygromycin concentrations of 50–250 mg l⁻¹ were used for selection in tall fescue. In some cases, a stepwise increase in hygromycin concentration (e.g., from 50 to 200 mg l⁻¹ for perennial ryegrass and from 25 to 100 mg l⁻¹ for Italian ryegrass) and a doubling of the selection pressure in every 2-week subculture step were used to recover resistant calluses (Spangenberg *et al.*, 1995b; Ye *et al.*, 1997). It should be noted that different cultivars and genotypes could have different levels of endogenous tolerance to antibiotics, which might lead to the recovery of escapes if not enough selection pressure is applied.

2.4 Regeneration of Whole Plant

For both biolistic transformation and *Agrobacterium*-mediated transformation, the identification and propagation of compact, yellowish/whitish, embryogenic calluses have been considered as key factors affecting transformation frequency (Xiao and Ha, 1997; Spangenberg *et al.*, 1998b; Zhang *et al.*, 2003; Li and Qu, 2004; Luo *et al.*, 2004; Dong and Qu, 2005; Wang and Ge, 2005a). The use of nonmorphogenic cultures only allowed the generation of resistant callus lines but not transgenic plants (Hensgens *et al.*, 1993; van der Maas *et al.*, 1994).

The establishment of an efficient plant regeneration system from embryogenic cultures is a prerequisite for stable transformation. In most of the reports, embryogenic calli were first induced and then used for particle bombardment or for incubation with *Agrobacterium*; resistant calluses were obtained after several weeks of antibiotic selection. In general, if highly embryogenic cultures were used for transformation, transgenic plants could be regenerated from the resistant calluses.

2.5 Testing of Transgenics

Detailed molecular analyses should be carried out to demonstrate the stable integration and expression of the transgenes in grasses. Insufficient molecular characterization may have contributed to the lack of reproducibility of some reports. Southern hybridization analysis, Northern hybridization analysis, enzyme assays, or other data confirming the functionality of the transgene should be provided (Wang *et al.*, 2001).

Transmission of foreign genes to progenies is critical for any potential use of transgenic material for producing novel germplasm. Because of the outcrossing nature and vernalization requirement of most of the cool-season grasses, only limited information is available on transmission of foreign genes in plants obtained by biolistic and *Agrobacterium*-mediated transformation (Spangenberg *et al.*, 1998b; Wang *et al.*, 2003a; Wang and Ge, 2005a).

The meiotic transmission of transgenes was studied in selected transgenic tall fescue and Italian ryegrass plants after reciprocal crossings

with wild-type untransformed control plants (Spangenberg *et al.*, 1998b; Wang *et al.*, 2003a; Wang and Ge, 2005a). T₁ seedlings of transgenic tall fescue and Italian ryegrass obtained by particle bombardment and transgenic tall fescue obtained by *Agrobacterium*-mediated transformation were subjected to polymerase chain reaction (PCR) and southern hybridization analyses. Expected 1:1 segregation ratios of the transgenes were observed in screened T₁ seedlings from independent T₀ transgenic plants. The results demonstrated stable meiotic transmission of the transgenes following Mendelian rules in transgenic grass plants obtained by biolistic or *Agrobacterium* transformation.

Transgenic forage-type tall fescue plants were transferred to the field and evaluated regarding their agronomic performance and pollen viability (Wang *et al.*, 2003b, 2004b, c). Although agronomic performance of the primary transgenics was generally inferior to the seed-derived plants, no major differences were found between the progenies of transgenics and the progenies of seed-derived plants (Wang *et al.*, 2003b). Progenies of primary transgenics had similar pollen viability when compared with that of seed-derived plants (Wang *et al.*, 2004b). The results indicate that once seeds are obtained from the primary transgenic plants, normal pollen viability and agronomic performance of the progenies can be expected. No indication of weediness of the transgenic tall fescue plants was observed. The field study provided evidence that outcrossing grass plants generated through transgenic approaches can be incorporated into forage breeding programs.

2.6 Specific Regulatory Measures Adopted

Prior to 2005, field trials of transgenic forage grasses required only a notification to APHIS (Animal and Plant Health Inspection Service) of USDA. Since 2005, field release of outcrossing transgenic grasses has been much tightened, requiring permit application, environmental assessment, and public comments. The major concern is pollen-mediated transgene flow in outcrossing grasses. Because human consumption is indirect, biosafety evaluation of transgenic grasses will likely to focus on their environmental or ecological impacts. Two questions need to be

answered regarding biosafety of transgenic grasses. First, how far can grass pollen disperse and still remain viable, and second, what is the probability of transgene escape by crossing with related grass species under natural conditions? Rigorous scientific studies using convincing molecular techniques are urgently needed to answer these questions.

3. FUTURE ROAD MAP

3.1 Expected Products

With the development of transgenic technologies in forage grasses, efforts have been made to produce transgenic plants with improved agronomic characteristics or evaluate novel strategies for molecular breeding. One of the most promising aspects is to genetically modify lignin biosynthesis to improve digestibility of forage grasses.

Lignification of cell walls during plant development has been identified as the major factor limiting digestibility of forages (Buxton and Russell, 1988; Buxton and Redfearn, 1997; Vogel and Jung, 2001). Feeding and grazing studies have shown that small changes in forage digestibility can have a significant impact on animal performance (Vogel and Sleper, 1994; Casler and Vogel, 1999). Lignin in forage grasses comprises guaiacyl (G) units derived from coniferyl alcohol, syringyl (S) units derived from sinapyl alcohol, and *p*-hydroxyphenyl (H) units derived from *p*-coumaryl alcohol. Transgenic modification of lignin biosynthesis has been well studied in dicot species, such as tobacco, *Arabidopsis*, alfalfa, and poplar (Baucher *et al.*, 1998; Dixon *et al.*, 2001; Humphreys and Chapple, 2002; Reddy *et al.*, 2005). In grasses, it has been shown that down-regulation of CAD and COMT led to altered lignin and significantly increased *in vitro* dry matter digestibility of transgenic tall fescue (Chen *et al.*, 2003, 2004). Genetic modification of lignin has been considered to be of low risk because it is unlikely that lignin reduction will increase plant fitness (Bradford *et al.*, 2005). Engineering of such a low-risk trait is likely to reduce biosafety concerns of transgenic grasses.

The development of hypo-allergic grasses is another interesting approach. Grass pollen is a

widespread source of airborne allergens and is a major cause of hayfever and seasonal allergic asthma. The introduction of antisense *Lol p1* and *Lol p2* transgenes into ryegrass plants led to the reduction in accumulation levels of *Lol p1* and *Lol p2* allergens in pollen, as demonstrated by immunoblots using polyclonal antibodies raised against the recombinant *Lol p1* and *Lol p2* allergens as well as with sera from grass pollen sensitized patients (Petrovska *et al.*, 2004). The development of hypo-allergenic grass cultivars will have tremendous benefits for public health.

It is feasible to improve many other traits in grasses by transgenic technologies, such as tolerance to drought, cold, salt, diseases, and insects. Risk assessments for such traits will probably be very demanding.

3.2 Addressing Risks and Concerns

Pollen-mediated gene flow in outcrossing grasses is a natural process that has happened in the past and will continue to happen in the future. The introduction of transgenic techniques has brought new attention to the process and raised both ecological and economic issues for scientists and policymakers to consider. As novel transgenic grasses are tested and grown in the field, preventing unwanted gene flow will present technical and regulatory challenges as well as possible economic conflict (Wang *et al.*, 2004d). In recent years, strategies have been developed to allow desired traits to be obtained through precise genetic modification within the plant's own genome rather than through introduction of genetic variation from unrelated species (Nielsen, 2003; Rommens *et al.*, 2004). By cloning genes and promoters from a species and reinserting the sequences into the same species, no new genetic information is introduced into the transgenics from other species. Such strategy can be easily utilized for the effective improvement of some traits, such as digestibility by lignin modification or down-regulation of pollen allergens.

To limit pollen-mediated gene flow in transgenic grasses, development of nonflowering plants or male-sterile materials are obvious strategies. However, such strategies need to overcome the challenges of seed production and economics of commercialization.

3.3 Future Prospects

With the availability of more and more gene sequencing information, such as expressed sequence tags (ESTs), gene isolation has become easier than ever before. Functional characterization of genes and their gene regulatory elements has become the major bottleneck. Although much progress has been made in developing transformation methods in the last decade, the production of transgenic grasses is still time consuming, laborious, and inefficient. There is a great need to improve transformation efficiency in the important forage grasses and thus allow the production of large numbers of transgenic plants in a relatively short time. In view of the rapid development and improvement of transformation methods for different grasses in the last decade, it is foreseeable that further optimization of the *Agrobacterium* or biolistics-based methods will lead to more efficient and refined transformation systems in the near future.

Transgenic technologies developed for forage grasses have opened up new opportunities for molecular breeding of these species. The major challenge now is how to apply the technology to produce new germplasm and cultivars that satisfy regulatory requirements. By efficient incorporation of novel materials into applied forage grass breeding programs, it is expected that transgenic technology will accelerate the development of landmark cultivars in the 21st century.

Bahiagrass

Fredy Altpeter, Mrinalini Agharkar and Sukhpreet Sandhu

Agronomy Department, Plant Molecular Biology Program, Genetics Institute, University of Florida—IFAS, Gainesville, FL, USA

1. INTRODUCTION

Bahiagrass (*Paspalum notatum* Flüggé) is a perennial, warm-season turf and forage grass, with wide distribution in the tropical and subtropical regions of the world. Bahiagrass is one of the most drought-tolerant grasses due to an extensive root system. It performs well in infertile, sandy soils and does not require high inputs. Unlike many other warm season grasses, bahiagrass produces large amounts of seeds. Bahiagrass resists most pests and diseases, and tolerates overgrazing. Main targets for genetic improvement of bahiagrass include forage quality, turf quality parameters including seedhead suppression, leaf texture, turf density, further enhancement of its abiotic stress tolerance and low input characteristics, mole cricket, and herbicide resistance.

1.1 Origin, Distribution, and History

Species of the genus *Paspalum* are abundant in the tropical and warm temperate regions, especially Brazil, eastern Bolivia, Paraguay, and northeastern Argentina. This South American center of diversity is believed to be the center of origin of the species (Gates *et al.*, 2004). “Pensacola”, the predominantly used diploid cultivar of bahiagrass belongs to *P. notatum* var. *saurae*. The var. *saurae* types are native to Corrientes, Entre Rios and the eastern edge of the Santa Fe Provinces in Argentina, and

large natural populations with genetic diversity were found in these areas (Burton, 1967). Common autotetraploid bahiagrass races like the popular cultivar “Argentine” share homologous chromosomes with races of var. *saurae*.

“Pensacola” bahiagrass is found in most countries of the western hemisphere. Several South American countries use the cultivars “Pensacola” and the derived cultivar “Tifton 9” for forage as well as turf purposes. Bahiagrass plantings are found in southern Brazil where it is an important forage crop. In the United States, “Pensacola” bahiagrass escaped from cultivation and has become naturalized in the southeastern States. The tetraploid races of bahiagrass are found in a wide variety of habitats such as open areas, savannas and cultivated pastures in central Mexico, Argentina, and throughout the West Indies. Common bahiagrass is found as the primary constituent in many native pastures in southern Brazil, Paraguay, Uruguay, and northeastern Argentina. Australia has naturalized populations of both “Pensacola” and tetraploid races. Bahiagrass is used in pastures in southwestern Japan. In addition, the use of bahiagrass is being explored in Taiwan and Zimbabwe. Thus bahiagrass is widely distributed in tropical and subtropical regions of the world.

The Bureau of Plant Industry (SPI No. 35067, Office of Foreign Seed and Plant Introductions) first introduced bahiagrass in the United States in 1913 (Scott, 1920). Seeds from Cuba were used to establish the first experimental plantings in Georgia in 1930. Seeds of “Argentine” bahiagrass

and “Paraguay 22” bahiagrass arrived in 1944 and 1947, respectively and were distributed for testing by United States Department of Agriculture (USDA) and the Florida Experimental Agriculture Research Station. “Pensacola” bahiagrass seeds probably arrived on a ship from Argentina before 1926 and were first found growing near the docks in “Pensacola”, FL (Burton, 1967). The introduction and use of “Pensacola” bahiagrass for pastures in the southeastern United States was a major achievement (Hoveland, 2000). “Pensacola” bahiagrass is more cold tolerant than “Argentine” and grows throughout the southeastern United States, from Texas to North Carolina, and extends into Arkansas and Tennessee. “Pensacola” bahiagrass was even reported in southeastern Oklahoma and Virginia (Gates *et al.*, 2004) but it shows a low productivity and persistence in colder environments.

1.2 Botanical Description

1.2.1 Taxonomy

Bahiagrass was first described using a plant collected by Schrader and Ventenat from St. Thomas Island in 1810. It is classified as *P. notatum* Flüggé. There are several synonyms including *Paspalum saltense* Arechavaleta, *Paspalum uruguayense* Arechavaleta, and *P. notatum* var. *latifolium* Doell. The common names used in different countries are bahiagrass (United States), pasto horqueta (Argentina), capii cabayu (Paraguay), and grama batatis (Brazil). The sexual diploid form is classified as *P. notatum* var. *saurae* Parodi. It is also known as *Paspalum sauræ* (Parodi) Parodi (Gates *et al.*, 2004).

1.2.2 Habit

Bahiagrass is perennial, with strong, shallow, horizontal rhizomes that have short, stout internodes. The internodes are usually covered with old, dry leaf sheaths. Culms are simple, ascending, geniculate at the node between the first and second elongated internodes, otherwise erect, 10–60 cm tall. Leaves are mostly crowded at the base with overlapped keeled sheaths, glabrous, or with ciliate margins mainly toward the summit. Blades are usually flat or somewhat folded toward

the base, linear lanceolate 3–30 cm long, 3–12 mm wide, usually glabrous or ciliate toward the base and rarely pubescent throughout. Subconjugate inflorescences emerge as a 60–90 cm long stalk with a short almost imperceptible common axis of typically two 3–14 cm long racemes (rarely three). Racemes are ascending or recurved-divergent in some races. The rachis is glabrous, flexuous, and green or purplish. Spikelets are solitary in two rows on one side of the rachis, obovate or ovate, shining, glabrous, 2.5–4 mm long and 2–2.8 mm wide. Anthers and stigmas are usually purple, the fruit is oval about 1.2–1.8 mm wide (summarized from Gates *et al.*, 2004).

On the basis of botanical characteristics, common, tetraploid bahiagrass is the typical form of *P. notatum*, characterized by broad leaves, strong roots, and stout rhizomes with short internodes. When compared to common, tetraploid bahiagrass, the diploid “Pensacola” type is taller, with longer and narrower leaves, smaller spikelets, and more racemes per inflorescence. It belongs to *P. notatum* var. *sauræ*.

1.2.3 Cytological features

The base chromosome of bahiagrass is $x = 10$. Ploidy levels in the wild range from diploid ($2n = 2x = 20$) to pentaploid ($2n = 5x = 50$). The botanical variety *P. notatum* var. *sauræ* comprises all races with $2n = 2x = 20$, commonly known as “Pensacola” bahiagrass. Studies of chromosome numbers of naturally occurring bahiagrass accessions from South America revealed that most of them were tetraploids ($2n = 4x = 40$), with a few diploids ($2n = 2x = 20$), one triploid ($2n = 3x = 30$), and one pentaploid ($2n = 5x = 50$) (Gates *et al.*, 2004). Diploids found in “Argentine” were considered indigenous, while those found in Brazil were escapes from cultivated pastures. Pentaploids ($2n = 5x = 50$) and hexaploids ($2n = 6x = 60$) have been created artificially by pollinating apomictic tetraploids ($2n = 4x = 40$) with pollen from diploids and tetraploids, respectively, by the fertilization of an unreduced egg ($2n + n$) (Burton 1948; Martínez *et al.*, 1994). Tetraploid plants have been produced by doubling the chromosomes of diploid plants by colchicine (Forbes and Burton, 1961a). Octaploid plants with 80 chromosomes have also been produced from tetraploid plants using the same approach (Quarin, 1999).

The tetraploid races are believed to have originated by autopolyploidy. Evidence for this was provided by chromosome pairing studies carried out in induced sexual autotetraploids, natural apomictic tetraploid strains, and sexual \times apomictic tetraploid hybrids (Forbes and Burton, 1961b). It has been observed that in the pollen mother cells (PMC) of tetraploid plants, the chromosomes pair primarily as multivalents during meiosis I, forming 2–10 quadrivalents (Forbes and Burton, 1961b; Fernandes *et al.*, 1973). Also, triploid hybrids from crosses between diploid and tetraploid plants have as many as ten trivalents per PMC during meiosis I. This indicates that there is complete homology between the genomes of the diploid parent and both genomes of the tetraploid male parent (Forbes and Burton, 1961b). These data provide evidence for the assumption that *P. notatum* is an agamic complex containing many cytotypes with different ploidy levels, mostly autotetraploids.

1.3 Economic Importance

Bahiagrass is widely used in tropical and subtropical regions of the world including southwestern Japan, South America, and the southeastern United States, covering an estimated 5 million acres in Florida alone. The primary use of Bahiagrass is for forage, in Florida alone, bahiagrass supports about 1.2 million head of beef cattle. In addition it is also popular as utility or low-input turf. Bahiagrass is well adapted to sandy soils and remains productive with low fertility and low pH. It also tolerates periodic flooding. Bahiagrass is one of the most drought tolerant grasses due to its extensive root system. Bahiagrass has very few disease and pest problems. Mole crickets and fall armyworms may cause some damage. Ergot may reduce seed yields, even though damage is usually minimal (Blount *et al.*, 2002). The rhizomes of bahiagrass store large amounts of organic and inorganic nutrients and contribute to the persistence of the species.

1.3.1 Production

Bahiagrass, in contrast to many warm season grasses, is an abundant seed producer. Due to dor-

mancy, seed germination typically occurs slowly over a period of time (West and Marousky, 1989). In addition, seedlings are not very competitive against weeds (Williams and Webb, 1958). Hence the scarification of seeds to break the dormancy, preparation of a good seedbed and careful seed placement is important for quick establishment of a new bahiagrass stand (Burton, 1939, 1940). In Florida, the six warmest months of the year (April–September) comprise the major growing season and account for more than 85% of the annual production (Beatty *et al.*, 1980; Mislevy and Everett, 1981). Day length and temperature play important roles in the productivity of bahiagrass in subtropical and more temperate regions (Gates *et al.*, 2004). Following shorter days and the first freeze events bahiagrass becomes dormant, and alternative forage like cool season grasses becomes necessary to support the cattle industry. The timing of nitrogen application has an impact on the herbage accumulation pattern (Beatty *et al.*, 1980). Bahiagrass pastures are easy to manage as they tolerate overgrazing. However, the forage quality is comparatively low due to relatively low protein content and antinutritional factors. The antinutritional factors include secondary metabolites such as tannins, alkaloids, and phenolic compounds (e.g., lignins) or structural components of cells and tissues (Gates *et al.*, 2004). Bahiagrass can tolerate intense grazing and clipping (Sampaio and Beatty, 1976).

The tolerance of bahiagrass to drought conditions, periodic flooding, and light sandy soils with low fertility makes it desirable as forage and low-input turf. However, bahiagrass does not tolerate severe cold temperatures. This limits production and use in transition zones to temperate climate.

1.3.2 Crop rotation

Bahiagrass is also valuable in crop rotations. The use of bahiagrass has been reported to effectively control the population of root-knot nematodes of peanut (Rodriguez-Kabana *et al.*, 1988). Reduction in the incidence of stem rot and limb rot in peanut was reported following rotation with bahiagrass (Johnson *et al.*, 1999). Similarly, there was a reduction in root diseases from *Rhizotonia solani* or *Pythium* spp. in snap bean and cucumber (Sumner *et al.*, 1999).

1.3.3 Seed production

This is a supplementary source of income on some ranches. An acre of bahiagrass can yield from 23 to 68 kg of clean seed (Chambliss and Adjei, 2002).

1.3.4 Hay

If bahiagrass is harvested prior to flowering, it can provide good quality hay. However, harvesting at this stage may be difficult because the grass is low growing and dense. Usually surplus growth on pastures is cut and sold as hay (Chambliss and Adjei, 2002).

1.3.5 Sod production

Sod provides a popular alternative to seeds for establishment of new lawns. Lawns are established quicker by using sod, and establishment success is not dependent on seed quality and less dependent on environmental factors. Typically well-established pastures are utilized for sod production. Bahiagrass is the predominant utility turf grass, planted along highway right-of-ways throughout the southeastern United States and is used as low-input lawn grass in large turf areas. It has an excellent persistence and low or no irrigation requirement. The major disadvantage as turf is the prolific production of 60–90 cm tall seedheads throughout the fall and summer months, requiring frequent mowing. “Argentine” is the preferred cultivar for use as turf because it forms a denser turf and has a shorter period of seedhead production compared to “Pensacola.”

1.4 Traditional Breeding

Breeding efforts for bahiagrass have been focused on the sexual diploid germplasm, “Pensacola.” The naturally occurring tetraploid cultivars are apomictic and hence options for their genetic improvement are very limited. The generation of sexual tetraploids by doubling the chromosomes of diploid plants using colchicine allows for unidirectional gene transfer from such apomictic cultivars to sexual tetraploids (Forbes and Burton,

1961a). The tetraploid cultivars used at present are superior ecotypes selected from the introduced germplasm (Gates *et al.*, 2004). Seed for the following cultivars is available commercially: “Argentine”, “Paraguay”, and “Paraguay 22.” The most important breeding objective for bahiagrass has been above ground biomass yield. Two approaches have been used to improve bahiagrass. In the first approach, inbred lines of “Pensacola” were established in alternate rows in a field and the F₁ seeds were collected. “Pensacola” is partially self-incompatible. Hence most of the seeds resulted from out crossing (Burton, 1974). This approach was not very efficient since establishing the seed production fields from vegetatively propagated clones is very labor intensive.

The second approach was called “restricted recurrent phenotypic selection” (RRPS), a modification of the mass selection procedure (Burton, 1974). Selection was started from an initial population collected from 16 farms in Georgia. Twenty-three cycles of selection for increased forage production were completed by this approach. In this procedure, 1000 space-planted individuals were used for selection and 20% of these were selected based on scoring for above ground herbage accumulation. They were intermated in a polycross to produce seeds for the subsequent selection cycle. Seeds from the polycross were germinated in the greenhouse during winter and transferred to the field during spring. “Tifton 9” was released as a cultivar from the ninth selection cycle. Bahiagrass is characterized by a seasonal reduction in forage quality with an increase in fiber concentration. This results in low forage quality, i.e., *in vitro* dry matter digestability (IVDMD). Procedures similar to RRPS were used to select for increased yield and IVDMD. During seed germination in the winter in the advanced selection cycles, it was found that high yielding selections also showed early germination and reduced dormancy (Gates and Burton, 1998). Low forage production in the fall and winter months poses severe problems for dairy and beef cattle production in the southeastern United States. Selections for higher yield using RRPS also had a changed day-length response and more advanced cycles showed less response to supplemental light. Gates *et al.* (2001) suggested that this might result in higher growth rates of the advanced cycles during the cool season when day length is short.

A 2-year study in Quincy, FL indicated distinct cycle differences in sensitivity to day length (Blount *et al.*, 2001). It also identified day-neutral plants and also plants that could tolerate temperatures of -4°C . This was a significant achievement since improving cold tolerance is also one of the main breeding objectives for bahiagrass. Breeding effort was also directed to reducing the time taken for stand establishment and the improvement of forage quality and seedling vigor (Blount *et al.*, 2001).

“AU Sand Mountain” bahiagrass (*P. notatum* var. *saurae*) is a recent release of Auburn University. This is a natural selection of an introduction planted at the Sand Mountain Substation (Crossville, AL) about 30 years ago. It is characterized by narrow leaves, fine tillers, and shorter inflorescences. This variety has been shown to yield more than “Argentine”, “Pensacola”, Tifton 9, and even bermudagrass.

Evaluation of related germplasm is another activity being carried out at the University of Florida (Blount *et al.*, 2001). This includes new *P. notatum* accessions as well as *Paspalum* species. A genetic linkage map for diploid *P. notatum* has recently been constructed (Ortiz *et al.*, 2001). This map was developed as a framework for genetic studies as well as breeding purposes. The map was created using heterologous restriction fragment length polymorphism (RFLP) clones from maize, rice, and oat. The creation of this map will make it possible to study complex and simple traits and should prove to be a useful tool for plant breeders.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

In the case of diploid cultivars, introgression of desired traits by traditional hybridization or identification of superior ecotypes has been successful. However, genetic variability for the desired trait is necessary for the success of this approach. Transgenic technology may help to expand bahiagrass improvement to include traits that are difficult or impossible to incorporate by traditional breeding like herbicide resistance or drastic improvement of forage and turf quality as well as cold tolerance.

Some of the most popular cultivars of bahiagrass like cv. “Argentine” are apomictic

tetraploids. This prevents their improvement using conventional hybridizations. The use of transgenic technology may help to overcome these problems. The apomictic nature of these tetraploid cultivars may prove to be an advantage for the generation of transgenic lines. In obligate apomictic types, there is no segregation resulting in a uniform seed progeny. Also the likelihood of unintended transgene dispersal by pollen is very low.

2. DEVELOPMENT OF TRANSGENIC BAHAGRASS

The genetic engineering of plants is largely dependent on the ability of cultured cells and tissues to regenerate whole plants, an efficient gene delivery system, and a selection protocol that helps to distinguish transgenic tissues and plantlets from nontransgenic tissue and plantlets at an early stage.

2.1 Traits of Interest

Most desirable traits for bahiagrass improvement include improvement of forage and turf quality, further enhancement of its abiotic and biotic stress tolerance and herbicide resistance. The containment of transgenes is also an important target for stress-tolerant perennial grasses.

2.2 Methods of Transformation

The first transgenic bahiagrass plants were produced by Smith *et al.* (2002) using biolistic gene transfer into a highly embryogenic genotype (Tifton 7) with no commercial relevance. Efficient selection and regeneration systems following biolistic gene transfer have been established for the commercially important cultivars “Argentine” (Altpeter and James, 2005), “Pensacola” (Gondo *et al.*, 2005), and “Tifton 9” (Luciani *et al.*, 2007). Two of the main advantages of biolistic gene transfer are that it efficiently supports co-integration and co-expression of multiple transgenes without vector backbone sequences, and that it is applicable to a wide range of genotypes (reviewed by Altpeter *et al.*, 2005). Sandhu and Altpeter (2008) reported a comparatively high co-integration and co-expression frequency

following biolistic gene transfer of two unlinked, linear, minimal expression cassettes lacking vector backbone sequences into apomictic bahiagrass.

Alternative gene transfer systems like *Agrobacterium*-mediated gene transfer (Hiei *et al.*, 1994) or protoplast-mediated gene transfer (Ha *et al.*, 1992) are applicable to a more limited number of genotypes and although these protocols were successful for the genetic transformation of a number of cereal and grasses, they have not yet been established for bahiagrass.

2.3 Selection of Transformed Tissue

In the first bahiagrass transformation report using the *bar* gene as selectable marker and 3 mg l^{-1} glufosinate as selective agent more than 90% of nontransgenic plants escaping the selection process were recorded (Smith *et al.*, 2002). The subsequent study by Gondo *et al.* (2005) replaced glufosinate with 3 mg l^{-1} bialaphos for selection of *bar*-transgenic bahiagrass plants and reported an escape rate of more than 50%. In a direct comparison of alternative selectable marker genes for bahiagrass transformation, James *et al.* (2008b) identified the *nptII* selectable marker in combination with the selection on paromomycin-containing medium during callus subculture and regeneration as superior to *bar* and bialaphos or *EPSPS* and glyphosate in transformation efficiency and suppression of nontransgenic plants escaping selection.

Following this *nptII*/paromomycin selection protocol several hundred transgenic bahiagrass plants have been produced so far. The *nptII*/paromomycin selection strategy has been reported to be successful in a range of monocotyledonous plants including ryegrasses (Altpeter *et al.*, 2000), fescue (Altpeter and Xu, 2000), and rye (Popelka and Altpeter, 2003). A number of alternative selectable markers have been reported for the transformation of other monocotyledonous plants and are reviewed by Miki and McHugh (2004). The strategy supporting the highest transformation efficiency with the lowest number of nontransgenic plants escaping the selection process can be combined with excision of selectable marker genes from transgenic plants following the selection process as reviewed by Hare and Chua (2002).

2.4 Regeneration of Plants

The genetic engineering of plants is largely dependent on the ability of cultured cells and tissues to regenerate whole plants following gene transfer and selection. Vimla Vasil and Indra Vasil described the first detailed accounts of embryogenic cultures from monocotyledonous plants (Vasil and Vasil, 1980) following the culture of meristematic tissues like immature embryos of *Pennisetum americanum* at a precisely defined stage of development on auxin-containing culture media. Modifications of these protocols made them applicable to a wide range of monocotyledonous species including cereals, turf, and forage grasses. Embryogenic bahiagrass callus was initiated from immature inflorescences (Bovo and Mroginski, 1986), young leaf tissue (Bienick, 1989), mature and immature embryos (Bovo and Mroginski, 1989), mature or germinating seeds (Marousky and West, 1990; Akashi *et al.*, 1993; Grando *et al.*, 2002; Altpeter and Positano, 2005; Gondo *et al.*, 2005). The donor plant or seed quality, culture media composition, amount of microparticles used for biolistic gene transfer, the developmental stage of the embryogenic target tissue at the time of bombardment and the concentration, type and timing of the selective agent, environmental conditions as well as the overall time in tissue culture determine plant regeneration efficiency, which highly correlates with the transformation efficiency.

2.5 Testing Transgenic Plants

Typically a few weeks after establishing the putative transgenic plants in soil, they are subjected to testing to confirm their transgenic nature. Amplification of a part of or the whole transgene sequence using polymerase chain reaction (PCR) provides a quick method for screening a large number of plants. Following PCR, expression analysis is carried out. This is done using reverse-transcriptase PCR (RT-PCR) and RNA as a template. Alternative screening procedures involve commercially available kits for expression analysis of common selectable marker genes like *bar* or *nptII* (Sandhu and Altpeter, 2008). In contrast to PCR-based methods, there are typically no false positives detected with such

Enzyme-linked immunosorbent assay (ELISA) or immunochromatography kits. The latter, however, has a relatively high detection limit and is not a quantitative assay. Further molecular characterization is carried out using Southern and Northern blots or real-time RT-PCR to estimate the number of copies of the transgene and level of expression, respectively. Plants that have been tested positive by molecular methods are then further evaluated for the expected phenotype under controlled environment or field conditions following approval by USDA-APHIS (Animal and Plant Health Inspection Services). The progeny of the transgenic plants is again subjected to molecular characterization to confirm stability of transgene expression.

2.6 Specific Regulatory Measures Adopted

Generation and evaluation of transgenic plants involve a regulatory procedure. The first step in this process is the Institutional Biosafety Committee (IBC), which oversees all applications for laboratory, controlled environment, and field testing of transgenic plants. The applications for work with genetically modified plants are first sent to the IBC for review. The IBC then inspects the facilities to check for compliance with safety guidelines. When the IBC preapproves an application for field evaluation of transgenic plants, they are forwarded to USDA-APHIS for final approval.

APHIS is a part of USDA that deals with transgenic organisms. Permit applications for field testing are sent to this agency for approval. The application should contain all the details of each transgenic line to be evaluated in the field including the source of the gene of interest, the expected trait, any molecular characterization data, field design, and the GPS co-ordinates of the proposed field site. USDA-AHPIS permit number 05-364-01r is currently supporting the field evaluation of genetically engineered dwarf bahiagrass to evaluate its turf quality and water use efficiency. USDA-APHIS permit number 05-294-01r is currently supporting the field evaluation of transgenic bahiagrass overexpressing stress-inducible transcription factors to evaluate its cold and drought tolerance. USDA-APHIS permit number 05-294-02r is currently supporting a risk assessment study, which evaluates short distance gene

transfer from transgenic, apomictic bahiagrass to different nontransgenic bahiagrass cytotypes. An environmental assessment for this study is available at <http://www.isb.vt.edu/biomon/releapdf/0529402r.ea.pdf>.

3. FUTURE ROAD MAP

3.1 Expected Products

In the last years, a large number of transgenic bahiagrass plants have been produced and several transgenic lines displayed desirable phenotypes. The introduction of a number of different transgenes in bahiagrass has resulted in plants with improved turf quality (Agharkar *et al.*, 2007; Zhang *et al.*, 2007), abiotic (Xiong *et al.*, 2006; James *et al.*, 2008a), and biotic (Luciani *et al.*, 2007) stress tolerance and herbicide resistance (Sandhu *et al.*, 2007).

3.1.1 Abiotic stress tolerance

Plant adaptation to abiotic stresses is dependent upon the activation of cascades of molecular networks involved in stress perception, signal transduction, and the expression of specific stress-related genes and metabolites. Engineering genes that protect and maintain the function and structure of cellular components as reviewed by Vinocur and Altman (2005) can enhance tolerance to stress.

Abiotic stress severely limits the productivity and persistence of forage and turf grasses like bahiagrass (*P. notatum* Flugge). Overexpression of a single stress-inducible transcription activator of the C/DRE stress response pathway CBF1(=DREB1B) or DREB1A(=CBF3) in transgenic *Arabidopsis*-enhanced freezing, drought, and salt tolerance with a concomitant expression of target genes (Jaglo-Ottosen *et al.*, 1998; Liu *et al.*, 1998; Kasuga *et al.*, 1999). The C/DRE stress response pathway is conserved in grasses (Jaglo *et al.*, 2001; Choi *et al.*, 2002; Dubouzet *et al.*, 2003). A *DREB1A* transcription factor ortholog was isolated from xeric, wild barley (*Hordeum spontaneum* L.) and introduced into the apomictic bahiagrass cultivar "Argentine" under control of the stress-inducible barley *HVA1s* promoter by James

et al., (2008a). The *HsDREB1A* gene was able to transactivate both the stress-inducible *HVA1s* and *Dhn8* promoters as shown with reporter gene assays in bahiagrass. *HsDREB1A* expression under control of the *HVA1s* promoter was detected in primary transgenic bahiagrass plants and their apomictic seed progeny by RT-PCR, real-time RT-PCR, and Northern blot analysis. Transgenic bahiagrass plants with stress-inducible expression of *DREB1A* survived severe salt stress and repeated cycles of severe dehydration stress under controlled environment conditions in contrast to nontransgenic plants (James *et al.*, 2008a).

The *WRKY* gene family represents a major group of plant-specific transcription factors implicated in many different processes (Eulgem *et al.*, 2000). The barley *Hv-WRKY38* transcription factor has been shown to be expressed during low temperature and freezing stress in an ABA-independent manner (Marè *et al.*, 2004). Transgenic bahiagrass lines with constitutive overexpression of the *Hv-WRKY38* transcription factor produced significantly more biomass than wild type following severe drought stress under controlled environment conditions (Xiong *et al.*, 2006).

The rice OsMYB4 transcription factor is strongly induced by low temperatures and has been shown to transactivate cold-inducible promoters (Vannini *et al.*, 2004). Overexpression of this gene in *Arabidopsis* significantly increased cold and freezing tolerance (Vannini *et al.*, 2004). Transgenic bahiagrass lines containing the above transcription factors have been generated and they are being evaluated under field conditions (USDA-APHIS permit number 05-294-01r) for enhanced cold and drought tolerance compared to wild-type 'Argentine' bahiagrass plants.

3.1.2 Biotic stress tolerance

Fall armyworm, *Spodoptera frugiperda* (J. E. Smith) is a destructive migratory pest of many tropical and subtropical grasses including bahiagrass. Engineering resistance to this pest in bahiagrass may further improve the potential of bahiagrass both as turf and forage. Bt toxins have been expressed in commercially important crops, such as cotton, soybean, and corn, to provide resistance to several lepidopteran pests.

To generate transgenic bahiagrass plants resistant to fall armyworm, a gene encoding an optimized, synthetic *Bacillus thuringiensis* endotoxin (Bt toxin) *cry1Fa* was subcloned under the control of the constitutive ubiquitin promoter. Co-transfer of constitutive *nptII* and Bt-toxin expression cassettes into seed-derived callus cultures from forage type bahiagrass cultivar Tifton, was carried out by biolistic gene transfer. Transgenic nature of the regenerated plants has been confirmed by PCR, Southern blot analysis, RT-PCR, and immunoassays. Neonate larvae fed with transgenic bahiagrass leaves showed a significant higher mortality than larvae fed with wild-type bahiagrass leaves (Luciani *et al.*, 2007).

3.1.3 Improvement of turf quality

Bahiagrass has several characteristics that make it desirable as low-input turf such as tolerance to drought, low fertility requirements, and few disease and pest problems. However, the turf quality of bahiagrass is reduced due to its open growth habit and prolific seedhead production during the fall and summer months.

In order to improve the turf quality of bahiagrass, a gibberellin-catabolizing enzyme, gibberellin 2-oxidase (*GA2ox1*) from *Arabidopsis* was introduced into bahiagrass under the control of the enhanced constitutive 35S promoter from cauliflower mosaic virus or the maize ubiquitin promoter with its first intron. Gibberellin 2-oxidases (*GA2ox*) are a family of enzymes involved in the degradation of bioactive gibberellins. These are 2-oxoglutarate-dependent dioxygenases (2ODDs) that inactivate bioactive gibberellins by hydroxylation of their C-2 (Martin *et al.*, 1999; Thomas *et al.*, 1999; Sakamoto *et al.*, 2001). Transgenic bahiagrass lines expressing the *GA-2* oxidase and displaying a semi-dwarf phenotype, while producing a larger number of tillers and showing delayed seedhead formation and reduced seedhead length, were identified under controlled environment conditions (Agharkar *et al.*, 2007). A field experiment has been established with these lines under USDA-AHPIS permit number 05-364-01r to evaluate turf density, seedhead production, mowing, and irrigation requirements.

Transcription factors involved in the control of flowering and cell expansion also have the

potential to contribute to improved turf quality. To evaluate this, the *Arabidopsis* repressor of cell expansion *ATHB16* has been overexpressed in bahiagrass under the control of the enhanced, constitutive 35S promoter. *ATHB16* (*Arabidopsis thaliana* Homeobox16) is a member of the HDZip family of plant transcription factors (Wang *et al.*, 2003). Transgenic expression of *ATHB16* in *Arabidopsis* resulted in alteration of flowering time, leaf expansion, and shoot elongation (Wang *et al.*, 2003). The *Arabidopsis* plants appeared dwarf with proportional reduction of leaf length and leaf width. Overexpression of the *Arabidopsis* *ATHB16* transcription factor in bahiagrass significantly changed plant architecture. Transgenic plants produced significant more vegetative and less reproductive tillers, shorter leaves, and shorter tillers. Overexpression of *ATHB16* resulted in proportional reduction of leaf width and leaf length. Formation of seedheads under natural photoperiod was delayed in some transgenic bahiagrass lines for approximately 4 weeks. Total root or shoot biomass and seed set were not compromised in semi-dwarf bahiagrass plants overexpressing *ATHB16* (Zhang *et al.*, 2007).

3.1.4 Herbicide resistance

Bahiagrass displays an open growth habit and slow establishment from seeds due to seed dormancy. Weed encroachment and low tolerance to commercially available herbicides make weed management a difficult task in bahiagrass. Fertile, herbicide-resistant transgenic bahiagrass lines from the apomictic cultivar “Argentine” were recently described by Sandhu *et al.* (2007). Integration of the constitutive *bar* gene expression cassette into genomic DNA of bahiagrass was confirmed by Southern blot analysis. Stable *bar* gene expression was detected by an immunochromatographic assay in primary transgenic lines and the apomictic progeny plants. Several independent transgenic lines showed no growth inhibition, chlorosis, or necrosis even after spray application of a solution with 1.0% glufosinate ammonium under greenhouse conditions. The selected transgenic plants did not differ morphologically from wild-type plants and produced viable seeds in the greenhouse and field (USDA-APHIS permit no.

05-365-01r). Transgenic plants resisted the field application of 0.6% glufosinate ammonium, which is twice the recommended rate for weed control, without any injury symptoms.

3.2 Addressing Risks and Concerns

Concerns about potential environmental risks involved with the commercialization of genetically modified turf or forage grasses currently slow their deregulation. Concerns associated with genetically modified (GM) grasses are putative invasiveness, vertical or horizontal gene flow, and other ecological impacts, like effects on biodiversity (Conner *et al.*, 2003). To address these concerns, risk assessment as well as development of containment strategies needs to be integrated into any grass biotechnology program.

3.2.1 Risk Assessment in transgenic bahiagrass

Perennial grasses containing genes that may contribute to enhanced fitness, such as stress protective genes, may display increased weediness or outcompete native species in natural areas. Hence, assessment of the relative fitness of transgenic plants under different environmental conditions can alleviate these concerns. Another important aspect of risk assessment studies is to monitor gene flow to predict the spread of transgenic plants in the environment. “Argentine” is a preferred bahiagrass cultivar target for genetic engineering, due to its apomictic reproduction mode, which contributes to uniform asexual seed progeny. However, “Argentine” bahiagrass produces viable pollen and there is a possibility of gene flow from the transgenic apomictic tetraploids to the sexual diploids. To address this, Sandhu *et al.* (2005b) are currently determining hybridization frequencies and gene flow between apomictic tetraploid bahiagrass and diploids under controlled environment and field conditions (USDA-APHIS permit number 05-294-02r) using Glufosinate resistance as a marker. The results of this study will provide an insight if apomixes in bahiagrass is a suitable natural transgene containment system.

3.2.2 Transgene containment strategies

The spread of transgenes through pollen, seeds as well as vegetative propagules can be reduced by transgene containment strategies. Although the apomictic nature of “Argentine” bahiagrass may provide an effective, natural containment system, concerns regarding the degree of sexuality of this species have prompted the consideration of alternative approaches to further enhance transgene containment. For perennial species, it would be desirable to have a system in place that would allow the selective elimination of transgenic plants, leaving the native species unharmed. The *ArgE* gene system (Kriete *et al.*, 1996) is an inducible cell death system, which may have potential for this purpose. The *argE* gene product of *Escherichia coli*, is an N-acetylornithin deacetylase, which converts nonphytotoxic N-acetyl-L.phosphinothricin (N-acetyl PPT) to phytotoxic phosphinothricin (glufosinate). Transgenic perennial ryegrass plants expressing the *ArgE* gene were shown to be selectively controlled by the application of proherbicide, N-acetyl-L.phosphinothricin (N-acetyl PPT) (Chen *et al.*, 2005). Transgenic bahiagrass plants expressing the *ArgE* gene have been generated and will be used to evaluate its potential as an environmentally neutral marker or inducible cell death system for selective elimination of transgenic plants (Sandhu *et al.*, 2005b).

3.3 Expected Technologies

Transformation technologies have made impressive progress since the first transgenic plants were produced. The development of an *Agrobacterium*-mediated genetic transformation protocol appears to be desirable for bahiagrass since it will, compared to biolistic gene transfer, likely enhance the frequency of single copy events, associated with a higher potential for transgene expression stability. Factors that need to be considered and optimized for monocots in order to establish an efficient protocol for *Agrobacterium*-mediated transformation have been reviewed by Cheng *et al.*, (2004).

While chloroplast transformation systems have been established for several dicotyledonous crops including cotton and soybean, homotransplas-

omic monocotyledonous plants have not been developed yet. Chloroplast transformation has made it possible to create plants with high levels of gene expression, while reducing line-to-line variation and also providing a natural transgene containment system, since chloroplasts are maternally inherited. The establishment of chloroplast transformation technology for bahiagrass can be based on the existing biolistic transformation protocol. In addition, the construction of vectors that support the integration of the transgene into the bahiagrass chloroplast genome by homologous recombination and high-level expression of selectable marker genes in nongreen plastids will be necessary.

The replacement of antibiotic resistance selectable markers by markers that provide cells a growth advantage in culture media containing mannose, xylose, or cytokinin glucuronides (reviewed by Joersbo, 2001) can alleviate some of the public concerns. Alternatively selectable marker derived from the host plant DNA like the mutant form of acetolactate synthase genomic DNA from rice could become available for genetic transformation of grasses. However, the use of antibiotic resistance genes will and should be continued if they support the highest transformation efficiency with the lowest escape rate. If elimination of antibiotic resistance genes is desirable, this strategy can be combined with excision of selectable marker genes from transgenic plants following the selection process as reviewed by Hare and Chua (2002).

The progress made in functional genomics of plants allows to predict and generate synthetic regulatory elements and transcription factors which will support the fine tuning of transgene and gene expression in bahiagrass.

RNA interference is a powerful technology for targeted gene silencing and will be useful to enhance forage quality in bahiagrass by down-regulation of genes in the lignin biosynthetic pathway and to engineer virus resistance.

3.4 Intellectual Property Rights (IPRs)

The University of Florida has filed a provisional patent application on the use of the *ATHB16* repressor of cell elongation for improvement of turf quality.

1. INTRODUCTION

Soybean, *Glycine max* (L.) Merr., is the most valuable grain legume crop, representing the primary source of protein and vegetable oil throughout the world. Currently global seed production is estimated at 217 million metric tons, with the major producers being the United States, Brazil, Argentina, and China. In the past decades, soybean crops have been improved significantly in agronomic traits such as yield, disease and pest resistance, and seed composition by both conventional and transgenic breeding methods. Global demand for soybean and soybean products is growing faster than ever, which in turn increases the demand for genetic improvements. Scientists have used biotechnology to meet this challenge by providing soybean with higher yield and seed quality. In this chapter, we describe the history of soybean development and distribution, trait improvement by conventional breeding, the advancement of transformation and transgenic traits, current and future soybean products, and new technologies in modern agricultural practices.

1.1 History, Origin, and Distribution

The soybean is often called the “miracle crop” because it is the world’s foremost provider of

protein and oil. Soybeans were domesticated between the 17th and 11th centuries BC in the eastern half of China where they were cultivated as a food crop. Soybean probably reached central and southern China and Korea by the 1st century AD. The movement of soybean germplasm within the primary gene center of China is largely associated with the evolvement of the China territories and Chinese dynasties (Hymowitz, 1970). Soybeans were subsequently introduced into several other countries including Japan, Indonesia, the Philippines, Vietnam, Thailand, Malaysia, Burma, Nepal, and India, aided by the establishment of sea and land trade routes (Hymowitz and Newell, 1980). These regions comprise a secondary gene center. The earliest Japanese reference to the soybean is in the classic *Kojiki* (Records of Ancient Matters), which was completed in 712 AD.

Soybeans were introduced to Europe in 1712 by Englebert Kaempfer, a German botanist who had studied in Japan. Swedish botanist Carl von Linne made the first scientific study of the soybean in the West. He named it *G. max* because of the unusually large nitrogen-producing nodules on its roots. Unfortunately, poor climate and soil conditions in Europe limited attempts to produce soybeans as a crop there. In 1765, Samuel Bowen introduced soybean from China into the Colony of Georgia and Henry Yonge planted soybean on

his farm at the request of Bowen (Hymowitz and Harlan, 1983). In 1767, Bowen received a royal patent for making soy sauce (Woodcraft, 1854) and James Mease was the first person in American literature to use the word “soybean” (Hymowitz and Shurtleff, 2005). Another early introduction of soybean into North America was by Benjamin Franklin in 1770 (Hymowitz and Harlan, 1983). In 1929, Morse spent 2 years doing research on soybeans in China, where he gathered more than 10 000 soybean varieties. It was not until the 1940s that farming of soybeans became widespread in America.

Today, more soybeans are grown in the United States than in any other country in the world. Farmers in more than 30 states grow soybeans, with the major producing states being Illinois, Iowa, Missouri, Minnesota, Indiana, and Ohio. Soybeans are the United States’ second largest crop in cash sales and the number one value crop for export. In 2004, US soybean farmers harvested 3.141 billion bushels (86 million metric tons) of soybeans. Nearly half of the total value of the US soybean crop was exported as whole soybeans, soybean meal, or soybean oil.

1.2 Soybean Biology

The soybean is a papilionoid legume (family Fabaceae, subfamily Faboideae), and a member of the tribe Phaseoleae, subtribe Glycininae. The genus *Glycine* is unique within the subtribe on several morphological and chromosomal characteristics, and does not seem to bear an especially intimate relationship with any other genus in the subtribe (Lackey, 1977). The genus *Glycine* is divided into two distinct subgenera: *Glycine* and *Soja*. The first consists of perennial species primarily from Australia. There are 22 recognized perennial species, of which *Glycine tabacina* and *Glycine tomentella* are neopolyploid ($2n = 78, 80$) (Hymowitz, 2004). The second consists of two annual species from Asia: *G. max* and *Glycine soja* Sieb. and Zucc. The first species is the cultivated soybean; the second species is the wild form of the soybean (Hymowitz, 2004). There are few cytogenetic barriers to gene flow between *G. max* and *G. soja* (Hymowitz, 1970; Hymowitz and Newell, 1981). Natural hybrids are easily produced at a relative low frequency by

Table 1 Soybean growth stages

Vegetative stages	Reproductive stages
VE (emergence)	R1 (beginning bloom, first flower)
VC (cotyledon stage)	R2 (full bloom, flower in top 2 nodes)
V1 (first trifoliolate)	R3 (beginning pod, 3/16" pod in top 4 nodes)
V2 (second trifoliolate)	R4 (full pod, 3/4" pod in top 4 nodes)
V3 (third trifoliolate)	R5 (1/8" seed in top 4 nodes)
V(n) (nth trifoliolate)	R6 (full size seed in top 4 nodes)
V6 (flowering will soon start)	R7 (beginning maturity, one mature pod)
	R8 (full maturity, 95% of pods on the plant are mature)

pollen flow from the cultivated soybean to the wild soybean during their simultaneous flowering with adequate pollinators (Nakayama and Yamaguchi, 2002). The cultivated soybean (*G. max*) is a predominantly self-pollinated species with an outcrossing rate of less than 1% (Chiang and Kiang, 1987). Soybean plants are thus virtually pure breeding homozygous lines, although manual cross-pollination is practiced routinely in breeding programs (Fehr, 1987). Soybean plants can be described in various growing stages (Table 1) during their development (McWilliams *et al.*, 1999).

Based on the timing of the termination of apical stem growth, soybean can be divided into two stem growth habits: determinate and indeterminate (Bernard, 1972). A determinate stem terminates apical growth abruptly and generally produces a thick stem tip. An indeterminate stem continues terminal growth as long as lateral growth continues, and produces a stem that is tapered in thickness from tip to base (Bernard, 1972). In the United States, there are 13 recognized maturity groups (MG) for cultivated soybeans, which range from MG 000, 00, 0, and I through X. Varieties with the lowest number designation (000 to IV) are considered indeterminate while maturity groups V through X are determinate varieties. Early maturing varieties (000 to IV) are adapted to the more northern climatic regions while later maturing varieties are more adapted to the south.

A single gene *dt1* was identified to be responsible for the stem growth type, with *dt1dt1* for the determinate, *Dt1Dt1* for the indeterminate, and *Dt1dt1* for the semi-determinate (Bernard, 1972).

A second locus *dt2* and a third allele (*dt1-t*) at the *dt1* locus were also determined to have effects on the stem growth phenotype (Bernard, 1972; Thompson *et al.*, 1997). In studying the effect of soybean stem growth habit on height and node number after beginning bloom in the midsouthern United States, Heatherly and Smith (2004) discovered that determinate MG V cultivars are capable of producing significant increases in height and node number after R1.

Leaves of soybean are alternate, pinnately trifoliate, with pulvini, stipels, and stipules (Lersten and Carlson, 1987). The nodulated root system is intermediate between a tap root type and a diffuse type. The soybean flower is a standard papilionaceous flower with a calyx of five united sepals; zygomorphic corolla of carina, alae, and vexillum; androecium of 10 diadelphous (9 + 1) stamens; and gynoecium of a single carpel. Twenty to sixty percent of the total number of flowers set pods in the cultivated type of soybean (Yoshida *et al.*, 1983). The reproductive success of flowers produced early in the period is usually greater than those produced later (Egli, 2005). However, more complete understanding is needed for the regulation of the temporal distribution of flower production or its potential role in determining pod and seed number at maturity (Egli, 2005). Although the higher production of flowers looks wasteful, data show that the flower production potential is more important for higher seed yield than the rate of reproductive abortion (Saitoh *et al.*, 1998). Generally, two to four seeds develop in the pods (Carlson and Lersten, 1987). The seeds have two large cotyledons and scant endosperm (Lackey, 1981), and are unique in their ability to accumulate high levels of both protein (40%) and oil (20%) (Fehr, 1987). Soybean seed has a short time frame for high germination and vigor (TeKrony *et al.*, 1987). Although the remaining seed from one crop is capable of germinating the following season, fresh soybean seed is produced annually for the next season in commercial operation.

Soybean descended from a diploid ancestor ($n = 11$) that underwent an aneuploid loss to $n = 10$ and subsequent polyploidization to yield the present genome with $2n = 2x = 40$ (Lackey, 1980). Genetic evidence of gene duplication suggests that soybean is a stable tetraploid with a diploidized genome. The soybean genome

comprises about 1.1 Mbp/C (Arumuganathan and Earle, 1991). This is about seven and a half times larger than the *Arabidopsis* genome, but less than one half the size of the maize genome. Singh and Hymowitz (1988) reported a complete karyotype of soybean based on pachytene analysis (<http://www.crops.cuiuc.edu/faculty/hymowitz/genlab/karyo.html>). About 40–60% of the soybean genome contains repetitive sequences (Goldberg, 1978; Gurley *et al.*, 1979), which was confirmed by the restriction fragment length polymorphism (RFLP) analysis. Approximately 90% of all RFLP probes detected duplicated loci and nearly 60% detected three or more loci in soybean (Shoemaker *et al.*, 1996). Hybridization-based mapping has resolved many duplicated regions of the genome. These homologous regions reflect segmental and whole-genome duplication events that can be used for the studies of the evolution of the genome. Analysis of bacterial artificial chromosome (BAC) end sequences suggests that although there are gene-rich and repetitive-rich regions, most regions contain a mixture of repetitive and genic sequences (Marek *et al.*, 2001). There is relatively low polymorphism in the soybean genome. Zhu *et al.* (2003) found that the rate of single nucleotide polymorphism (SNP) is 0.5 SNP/kb and 4.7 SNP/kb in coding and noncoding DNA, respectively, whereas maize has as much as 10-fold higher levels of nucleotide diversity (Ching *et al.*, 2002).

1.3 Economic Importance

Although soybeans are native to China, 40% of production is in the United States (Table 2). The United States produced 86 million metric tons of soybeans in 2004, of which more than one-third was exported. Other leading producers of soybeans are Brazil, Argentina, China, and India. Brazil became the world's largest soybean exporter in 2004. Much of the US production is used for animal feed, though consumption of soy food products has been increasing. In 2004, the United States planted 75.2 million acres (30.4 million hectares) of soybean, producing a record 3.141 billion bushels (86 million metric tons). The total 2004 crop value exceeded \$17.7 billion. The United States exported 1.1 billion bushels (29.94 million metric tons) of soybeans, which accounted for

Table 2 World soybean production in 2004^(a)

	Million metric tons	%
USA	86	40
Brazil	53	24
Argentina	39	18
China	18	8
India	6	3
Other	15	7
Total	217	100

^(a)Source: USDA (2005)

48% of the world's soybean trade and created \$8.0 billion revenue in 2004. China is the largest buyer of US soybean, importing \$2.3 billion in 2004. Japan was the second largest market for US soybean with purchases of \$1.0 billion. Other significant buyers included the European Union and Mexico. Canada was the largest customer for US soybean meal at \$300 million, followed by Mexico and the Philippines. Mexico was the largest customer for US soybean oil with purchases of \$63 million, followed by Canada with purchases of \$62 million.

China is one of the main soybean producing countries in the world. At the beginning of the 1990s, China operated as a pure soybean-export country, exceeding 1 million tons annually. Now, however, China has become one of the biggest soybean importing countries. According to the data provided by Chinese Customs, China's soybean import began to increase in 1999 and exceeded domestic production in 2003 for the first time. As China's soybean demand continues to grow, its import will keep rising. China's soybean consumption has outpaced increases in domestic production during the last 25 years mainly because of increases in consumption of soybean oil and meal induced by income and population growth, particularly in large urban areas. China has also been a major importer of soy oil for about 20 years.

Soybean can be utilized in a variety of ways, which can be divided into two groups: one based on the utilization of the whole seed, and the other based on products of soybean fractionation into oil and meal. Whole soybeans and their flour are used as ingredients in traditional confectionery products and snacks in China, Japan, Korea, and Indonesia. Soy flour and grits are used in the commercial baking industry. They aid in

dough conditioning and bleaching. Their excellent moisture-holding qualities also help to retard staleness in baked products. Immature whole green seedlings are also consumed as a vegetable. Dried soybeans and bean sprouts are also consumed frequently in western countries and oriental cooking. Processed soybeans are also found in various food products including soymilk, soybean curd (tofu), tofu-based ice cream, soybean yogurt, soybean paste (miso), soy sauce (sho-yu), tempeh, and fermented soybean curd (su-fu).

Processing soybean results in two fractions: oil and meal. Different grades of oil can be produced through a series of refining processes. More complete hydrogenation of soybean oil is the basis for the manufacture of shortenings, margarines, and tailor-made fats used by various food industries.

After removal of the soybean oil, the remaining flakes can be processed into various edible soy protein products or used to produce soybean meal for animal feed. The largest portion of the soybean meal and cake production is used as a protein source in animal feed. The different types of soybean meal are characterized mainly by their protein content and the extent of heat treatment applied during their production to inactivate antinutritional factors. If the soybeans are extracted without dehulling, or if the hulls are added back after extraction, the meal will contain about 44% protein. Meals produced from dehulled beans contain approximately 50% protein.

There are also soybean meal products for human use. Eight essential amino acids are found in soybeans, which are necessary for human nutrition because they are not produced naturally in the body. These amino acids can be added to the human diet in products including soybean protein concentrates, soybean protein isolates, and extrusion-textured soybean protein. Soybean protein can also be spun into a silklike fabric.

Soybean oil has also recently been employed for industrial purposes, opening up a large new market for soybeans. More than 600 million pounds of the soybean oil produced annually in the United States are used for nonedible applications including fatty acids, soaps, paints, varnishes, resins, printing inks, lubricants, surfactants, cleaning solvents, and biodiesel (Marking, 1998). Soy biodiesel represents the largest potential industrial use of soybeans. It is the most flexible, lowest cost alternative fuel

option for diesel fleets. Soy-based biodiesel is made by a chemical process called transesterification. This process results in biodiesel and a by-product called glycerine that has more than 1600 commercial applications from toothpaste to environmental-friendly antifreeze. Biodiesel fuel does not require expensive vehicle modifications or fueling equipment. B20, a mixture of 20% soy-based diesel and 80% petroleum diesel, has been approved by federal, state, county, and utility company vehicles under the Energy Policy Act of 1992 (EPACT) in the United States. Soybean also has the potential for making soy-based diesel fuel additives, which can provide superior lubricating properties. It was estimated that to realize a national goal of 4% renewable fuel use by 2016, soybean production would have to increase from 51 million bushels in 2002 to 318 million bushels by 2016. Commercial production of biodiesel in the United States is mainly through transesterification of soybean oil. A number of biodiesel manufacturing plants have been constructed in Austria, France, Italy, Germany, Denmark, Hungary, Sweden, Ireland, and the United States (National Renderers Association, 1992; Biodiesel Alert, 1993). The National Biodiesel Board reported production of 500 000 gallons in 1999. It is estimated that the demand for biodiesel will be at least 6.5 million gallons in 2010. The demand could be up to 470 million gallons in 2010 if combined with the demand for biodiesel as a lubricity additive (<http://www.eia.doe.gov/emeu/plugs/plbiodsl.html>). Brazil is currently using a new biofuel known as H-Bio. It is a mixture of cotton, castorbean, sunflower, and soybean oils (<http://www.blonnet.com/2006/07/02>).

The surfactant market has reached more than \$10 billion worldwide. Soybean oil is a good candidate for producing environment-friendly surfactants (Longhini, 1996). Soy ink has been on the market since 1987 in the United States. It is produced by slightly refining soybean oil and then blending in pigments, resins, and waxes. It has better resolution and improved mileage performance compared to the petroleum oil-based ink. Inks produced from soybean oil have reduced volatile organic compounds and do not contain polycyclic aromatic compounds, which are regulated by Environmental Protection Agency (EPA) due to the health risks associated with them

(Tao, 1994). Soy ink is also a helpful component in paper recycling. The soy ink can be removed more easily than regular ink, allowing the recycled paper to have less damage to its paper fibers and have a brighter appearance.

Soybean protein can be used to form flexible or more rigid plastics, which are used for food packaging purposes. These soybean-based plastics are biodegradable and are therefore safer for the environment than petroleum-based plastic, which are more persistent in the environment after disposal. The quickly degrading plastic may even help fertilize the soil as it naturally biodegrades. Another benefit of soybean-based plastic is the fact that it is made with a renewable resource. Recycling alternatives are also available for soybean plastic. It can be ground up after its first use and used in animal feed, or mixed together with waste paper to make composite building material that has the appearance of polished granite. This material could also be used in alternative wood products, such as a product called ENVIRON that is already available in the United States.

Soybean hulls also have high potential value. Each year, US soy processing generates 10–15 billion pounds of hulls that are typically sold to animal feed supplement producers for around \$40 a ton. Rather than using the hulls as a feed ingredient, scientists are working to convert them into ion exchange resins for use in adsorbent filters used to capture metals in solutions. Most commercial ion exchange resins cost between \$2 and \$20 per pound while the cost of the soy-based resins would drop to 53 cents per pound.

Soybean-based adhesive resin for the wood composite material industry has been developed (Kuo and Stokke, 2000). This product consists of defatted soybean flour cross-linked with synthetic phenol formaldehyde, the former typically at a ratio of 70% by weight of the adhesive resin. Testing has shown that the adhesive has performance characteristics between urea formaldehyde and phenol formaldehyde resins, which are the two most commonly used synthetic resins in the wood industry (Kuo *et al.*, 1998; Stokke and Kuo, 1999).

Some industrial applications of soybean require genetic enrichment of specific fatty acid components, for example, use of soybean oil as a renewable chemical feedstock. Researchers

at DuPont used genetic engineering approaches to create high oleic acid soybean (Kinney and Knowlton, 1998). High oleic oils are generally considered to be healthier than conventional soybean oil, and have potential uses in industry as discussed in Section 2.4.

1.4 Traditional Breeding

Traditional breeding has been used to modify the genetic make-up of plants and animals for many years. Using crosses to transfer the existing genetic variability or create new variability has been the major venue for traditional breeding (Liu, 1999). The goals of traditional soybean breeding are to develop varieties and germplasm with enhanced yield potential, resistance to biotic and abiotic stress, and improved chemical composition. Some specific objectives may include

1. Developing soybean varieties with resistance to soybean cyst nematode, *Phytophthora* root rot, sudden death syndrome, white mold, etc.
2. Developing varieties with tolerance to herbicides such as glyphosate, glufosinate, and sulfonyleurea.
3. Developing varieties with enhanced yield potential and adaptations to different environments.
4. Developing special varieties such as low linolenic acid, mid oleic acid, low phytate, high protein, etc.

Yield has been the single most important trait for breeders as it is the trait that has great impact on the farmer's bottom line. Typically, breeders use crosses between the parents of choice to create segregating populations. These populations are advanced either locally or at off-site nurseries with or without selection. Breeders use winter nurseries in Puerto Rico, Mexico, Central and South America, and elsewhere to obtain two, three, or more generations in a single season/year, advancing their breeding materials faster. Plant rows are then selected and are evaluated for desired traits primarily in the field; however, some disease traits are evaluated in greenhouses. A breeding cycle ends when the best pure lines are released.

Parent selection is the first and most important step in the breeding process. Parent selection can

be based on a number of different factors: traits of interest, genetic diversity, breeding objectives, complementarity of lines, and resources. Generally elite parents with diverse origin are more likely to produce superior progeny (Burton, 1997). Combining ability assessment of parents is also useful in identifying the best combination to exploit heterosis or combine fixable favorable genes that may lead to the development of superior genotypes (Agrawal *et al.*, 2005). By using a 5×5 diallel set of soybean crosses, Agrawal *et al.* (2005) showed that most plant characteristics might be governed by additive gene effects, however, the complexity of additive and nonadditive gene effects plays an important role in the expression of yield attributes.

Selection in breeding populations can be done during either early or late generation. These selection methods include: pedigree selection, single seed descent, and bulk breeding. Research has shown that the single seed descent coupled with concurrent selection for early maturity is the most efficient for development of early maturing cultivars (Byron and Orf, 1991). Bravo *et al.* (1999) compared family based and line-based pedigree methods in breeding for palmitate, and concluded that the line method is more effective. However, the bulk breeding method has been proven effective in improving yield in environments with disease pressure (Degago and Carviness, 1987).

Backcrossing has also been practiced widely to introgress favorable genes. Sometimes, *G. soja* has been used as a donor parent for small seed size, high protein content, or disease resistance traits. Recurrent selection has also been used in soybean to improve the frequency of favorable alleles in a population. It is a cyclic selection with each cycle having three steps: intermating, evaluation, and selection. A number of researchers have used recurrent selection to improve yield (Holbrook *et al.*, 1987; Piper and Fehr, 1987; Guimaraes and Fehr, 1989; Burton *et al.*, 1990; Werner and Wilcox, 1990; Rose *et al.*, 1992; Uphoff *et al.*, 1997). In general, recurrent selection is effective in soybean (Lewers and Palmer, 1997).

In order to create new genetic variation, mutagens such as ethylmethane sulfonate (EMS), x-rays, and fast neutron have been used to alter the soybean genome. Rahman *et al.* (1994) obtained a high oleic acid mutant line, M23, by using

x-rays on soybean variety Bay. M23 showed a twofold increase in oleic acid content compared with the original variety. The oleic acid content in this mutant was controlled by a single recessive allele, designated as *ol* at the *Ol* locus (Rahman *et al.*, 1996). Chemical mutagenesis was also used successfully to generate mutants with reduced linolenic acid levels (Hammond and Fehr, 1983; Bubeck *et al.*, 1989). Mutants A5 and A23 each had a single gene responsible for reducing linolenic acid content in the seed (Rennie and Tanner, 1991; Fehr *et al.*, 1992). Segregants with even lower linolenic acid content than the parents were identified in the crosses of A5 \times A23. These segregants were considered to have mutant genes from both A5 and A23 (Fehr *et al.*, 1992).

Mutagenesis has also been used to study root nodulation. A soybean supernodulation mutant, designated FN37, which lacks the internal autoregulation of the nodulation mechanism, was generated by fast neutron (Men *et al.*, 2002). Further characterization revealed that this mutant contains a chromosomal deletion. When inoculated with microsymbiont *Bradyrhizobium japonicum*, FN37 formed at least 10 times more nodules than the wild-type *G. soja* parent. Molecular markers were used to isolate BAC contigs delineating both ends of the deletion in FN37 mutant. Deletion break points were determined physically and placed within flanking BAC contigs.

Plant breeding has been practiced for hundreds of years via artificial selection. Selection has led to the highly improved performance of crop species. However, selection for quantitative traits has been difficult because the traits are affected by multiple genes (G), environments (E), and G \times G and G \times E interactions. In order to overcome these problems, marker-assisted selection (MAS) was developed as first described by Sax (1923). Further efforts identified associations of markers and quantitative trait loci (QTLs) in a number of species (reviewed by Paterson *et al.*, 1991). However, the lack of suitable markers hampered further development of this classical method. With the advent of molecular markers including RFLP, random amplified polymorphic DNA (RAPD), amplified fragment length polymorphism (AFLP), simple sequence repeats (SSRs), and SNP, systematic and accurate mapping of QTLs has become possible by the construction of molecular linkage maps.

Mapping of QTLs allows rapid identification of linked molecular markers, which then can be used to tag desirable alleles in segregating breeding populations. More directed genotypic selection of breeding lines should result in supplementing and possibly even eliminating phenotypic selection, especially for quantitative traits which are complicated, time consuming, and expensive to analyze.

To facilitate molecular breeding and other genomics research, the soybean community has constructed a composite genetic map, which contains 1845 markers (1010 SSRs, 718 RFLPs, 73 RAPDs, 23 classical traits, and 10 others) (P. Cregan, unpublished data). Over 319 QTLs for various agronomic and disease resistance traits have been mapped to the soybean genetic maps (Orf *et al.*, 2004). These identified QTLs and their linked molecular markers have greatly facilitated MAS in soybean. For example, using a patented molecular marker approach that combines biotechnology, robotics, and information management technologies, Pioneer Hi-Bred International, Inc. developed soybean cyst nematode (SCN) resistant soybean varieties effectively. MAS based on the location of SCN resistance genes mapped on specific chromosomes is used to confirm the presence of these genes in experimental varieties (Soper *et al.*, 2003). Markers have also been used to detect the presence of transgenes during the selection process.

In addition to the soybean genetic map, there is also a significant amount of soybean genomics resources available that will enhance soybean traditional breeding efficiency and ultimately increase soybean productivity. Over 300 000 soybean expressed sequence tags (ESTs) are in GenBank (<http://129.186.26.94/soybeanest.html>). Two soybean physical maps are constructed, one from soybean cv. Forrest (Wu *et al.*, 2004) and the other from cv. Williams (Warren, 2006). A wide variety of mapping populations and a variety of functional genomics tools (including DNA microarrays and proteomics resources) are also available. In addition, the United States Department of Agriculture/Agricultural Research Service (USDA/ARS) germplasm collection at the University of Illinois houses over 16 000 plant introduction lines from China and other parts of the world. Another collection of southern MG exists at the USDA/ARS facility in Stoneville, MS.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Breeders have been using conventional breeding methods to select favorable phenotypes for many years and have been making steady progress in improving soybean productivity. This method primarily utilizes the existing genetic variability to create new variability. There are a couple of limitations of the conventional breeding method: (1) linkage drag, i.e., often undesirable genes are transferred along with the desired ones in each cross, (2) the barriers for gene transfer through incompatibility, and (3) limited genetic variations available. With the increasing world population and increasing demand for soybean production, more advanced technology is necessary to meet the future needs. Research has been transformed by technologies that are allowing us to understand how genes work, and are providing a new level of understanding of how plants develop and function in their environments. The ability to isolate genes and transform them back into living organisms has greatly facilitated genetic improvement processes by directly modifying genetic make-up of important crops. The transgenic approach has made it possible to introduce desired foreign gene(s) into elite backgrounds. Transgenic breeding offers several advantages: (1) overcoming problems of sexual incompatibility, (2) introducing only the desirable genes without any linkage drag, (3) manipulating transgenes to create novel genetic variation. Transgenic soybean varieties carrying herbicide resistance gene have already been developed. The global transgenic soybean planting area reached 42 million hectares in 2003, which accounts for more than 55% of total soybean planting area and 61% of the planting area of transgenic crops (James, 2003). These transgenic soybeans have greatly improved soybean production efficiency and soybean value for end users.

Transgenic development is an extension of traditional breeding. Together, the two methods will enhance and improve the efficiency of plant breeding. Scientists can genetically engineer soybean plants with novel genes in the laboratory, but plant breeding is necessary to transfer the new transgenes through crossing into elite germplasm.

Genetically modified (GM) crops and the techniques of biotechnology offer huge benefits

in improving world food and nutrition supply, however, awareness must be created among the farming and consumer communities by the scientific community regarding their benefits in order for them to be more widely accepted.

2. DEVELOPMENTS OF TRANSGENIC SOYBEAN WITH IMPROVED TRAITS

With the rapid world population increase and the increasing demand for nutritious soybean products, it is imperative to increase soybean productivity and efficiency. Some major soybean producing countries have increased their production acreage; however, acreage increase alone will not be able to address this challenge due to the land availability. Biotechnology offers great potential by providing superior soybean products through genetic engineering. As illustrated by the examples in the following sections, biotechnology has changed the fundamentals of soybean production practices. Transgenic breeding has significantly increased soybean production efficiency and soybean product value through enhanced resistance to pests and herbicides, healthier and more nutritious soy foods and feeds, and new industrial opportunities for a more sustainable global environment. Genetic transformation is a key step in the transgenic breeding method; therefore, we will summarize the advancement of transformation methodology before illustrating the transgenic traits.

2.1 Soybean Transformation

Since the first reports of soybean transformation in 1988 (Hinchey *et al.*, 1988; McCabe *et al.*, 1988), advances in tissue culture and gene transfer have helped extend the technology to a number of academic and industrial laboratories around the world (reviewed in Dinkins *et al.*, 2003; Simmonds, 2003; Trick *et al.*, 2003; Clemente and Klein, 2004). Although soybean transformation is now more routine than in the immediate years following the first successful transformation reports, the technology is by no means standard and fully reproducible. Soybean transformation, and grain legume transformation in general, is considered more difficult than the transformation of other

crop species, such as rice and maize. Protocols for soybean transformation must be adapted and modified for development of a functional system in a particular laboratory. This is because efficient transformation systems require coupling three interlocking components. The first is the generation of tissues that are receptive to delivered DNA and capable of subsequent proliferation and regeneration to fertile plants. This requires growth and proliferation of cells and tissues in axenic cultures. Therefore, some expertise in plant tissue culture is required for soybean transformation. There are three routes for proliferation of soybean tissues *in vitro* that have been coupled with gene transfer procedures. Shoot organogenesis from mature cotyledons (Cheng *et al.*, 1980; Wright *et al.*, 1986), multiple shoot formation from apical meristems derived from mature seed (Kantha *et al.*, 1981), and somatic embryogenesis from immature cotyledons (Phillips and Collins, 1981; Lippmann and Lippmann, 1984). The second component of the transformation system is the method for delivering genes to the target tissue. Currently, soybean transformation relies on gene transfer mediated by *Agrobacterium* (Gelvin, 2003; Tzfira and Citovsky, 2006) or particle bombardment (Klein and Jones, 1999; Twyman and Christou, 2004). *Agrobacterium*-based systems rely on the organism's natural ability to transfer DNA to plant cells, while bombardment (or biolistics) uses DNA-coated particles to physically deliver genes directly into cells. The third component involves the means used to select transgenic tissue following gene transfer to the chosen target (Miki and McHugh, 2004). Genes that confer tolerance to chemical agents such as antibiotics or herbicides are generally co-introduced with trait genes (Miki and McHugh, 2004). Transgenic tissue can then be recovered after incubation in tissue culture medium containing the selective agent.

Each of these three components encompasses a number of variables, adding to the complexity of the transformation process and difficulties when attempting to replicate published reports. Currently the two most widely employed transformation approaches are delivery of DNA to cotyledonary node explants via *Agrobacterium* or particle bombardment for gene transfer to embryogenic suspension cultures. This review will discuss these approaches and describe how the components of transformation have been brought

together to develop alternative transformation systems.

2.1.1 Transformation using *Agrobacterium* and cotyledonary explants

Particular tissues from germinated seed provide suitable targets for transformation. The junction between the cotyledon and hypocotyls provide a source of axillary meristems when placed on the appropriate tissue culture medium (Cheng *et al.*, 1980). Wright *et al.* (1986) described procedures for regenerating fertile plants by organogenesis from cotyledons excised from seedlings. Following seed germination on tissue culture medium containing the cytokinin benzyladenine (BA), cotyledon explants were placed on medium containing BA. Preexisting meristems present at the base of the cotyledon, close to the hypocotyl junction, form multiple buds that go on to give rise to shoots. These shoots can be excised and placed onto root-inducing tissue culture medium. In one of the first reports of soybean transformation, *Agrobacterium* with transfer DNA (T-DNA) carrying a kanamycin or glyphosate resistance gene and a β -glucuronidase (GUS) gene for visual identification was co-cultivated with cotyledonary node (cot-node) explants. To accomplish this, the explants were simply incubated in a suspension of *Agrobacterium*. Transgenic shoots were recovered from regeneration medium containing sublethal concentrations of kanamycin and regenerated tissue was screened for GUS expression. About 6% of the recovered shoots were transgenic. Glyphosate tolerance and GUS expression was observed in T₂ progeny, demonstrating proper inheritance of the transgenes. The efficiency of the cot-node system as described in this first report is considered low (Olhoft and Somers, 2001), which is in part caused by low rates of DNA transfer to target cells, inefficient selection resulting in large numbers of escapes, and low rates of regeneration. Apparently the gene used to detoxify kanamycin by neomycin phosphotransferase (NPTII) provided a small growth advantage to transgenic shoots making it necessary to carefully screen all shoots surviving the selection. Di *et al.* (1996) also noted very low rates of transformation when employing kanamycin as the selection agent. The herbicide glyphosate was also used as a selection

agent in conjunction with a bacterial 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS) synthase gene that is insensitive to glyphosate (Clemente *et al.*, 2000), but rates of transformation were also low in this cot-node system.

Several groups have attempted to optimize the cot-node system to increase efficiency and extend the range of suitable genotypes. For example, Zhang *et al.* (1999, 2000) optimized the conditions used for co-cultivating the cot-node tissue with *Agrobacterium* and improved the media used for shoot elongation. These researchers also utilized the *BAR* gene for resistance to the herbicide glufosinate, which allowed for more effective selection of transgenic shoots than kanamycin resistance. The authors presented important details concerning the process, including the method used to prepare the explant for co-cultivation with *Agrobacterium*. Generally, efficient *Agrobacterium*-mediated gene transfer requires mechanical wounding of the explant, both to provide access to the sub-epidermal meristematic cells and as a means to stimulate production of inducer molecules that trigger the virulence genes of *Agrobacterium*. In this experiment, a scalpel was used to produce 7–12 vertical slices on the cotyledon very close to the cotyledon/hypocotyl junction. Following wounding, the explant was placed in a small petridish along with a suspension of *Agrobacterium*. Although the selection scheme with glufosinate was effective at culling the number of wild-type escapes, a number of the transgenic plants were chimeric, consisting of both transformed and nontransformed tissue. Transgenic plants were produced from about 3% of the treated cotyledon explants.

Further improvements in transformation efficiency were achieved by supplementing co-cultivation media with compounds that ameliorate the plant defense-response triggered by *Agrobacterium*. Thiol compounds, such as L-cysteine, increased rates of gene transfer to cot-node tissue (Olhoft and Somers, 2001; Olhoft *et al.*, 2001). This group employed L-cysteine in combination with hygromycin selection to achieve high rates of transgenic plant recovery (Olhoft *et al.*, 2003). About 16 transgenic plants were recovered from 100 explants infected with *Agrobacterium*. Other researchers have noted improved rates of soybean transformation caused by antioxidant supplements during *Agrobacterium*

transformation when using glufosinate as the selection agent (Paz *et al.*, 2004; Zeng *et al.*, 2004).

Other important factors influencing the efficiency of the cot-node system include genotype (Donaldson and Simmonds, 2000; Paz *et al.*, 2004) and *Agrobacterium* strain (Meurer *et al.*, 1998). Soybean genotypes differ in their ability to respond to tissue culture conditions and form shoots from the cot-node region. Soybean genotypes also vary in their capacity to interact and accept DNA from *Agrobacterium*. The heritability of susceptibility to *Agrobacterium* infection has been studied (Bailey *et al.*, 1994; Mauro *et al.*, 1995). One means to study the interaction of genotype and *Agrobacterium* is to infect cotyledons with *Agrobacterium* carrying a marker gene that can be scored visually. Meurer *et al.* (1998) found large differences in GUS expression between genotypes 45 days after co-cultivation with between 0% and 18% of the infected explants expressing GUS. Paz *et al.* (2006) noted a 4.5-fold difference between genotypes in their capacity to produce transgenic plants.

Early research (Byrne *et al.*, 1987; Delzer *et al.*, 1990) found significant strain-by-genotype interactions. Normally, gene transfer by *Agrobacterium* requires induction of bacterial virulence (*vir*) genes by phenolic compounds produced by wounded plant tissue. The *vir* genes reside on the Ti-plasmid and they function to excise the T-DNA region of the plasmid and promote its transfer and integration into the plant genome. Constitutive expression of *vir* genes in particular *Agrobacterium* strains can enhance gene transfer to soybean (Ke *et al.*, 2001).

Even the source of seed and the protocol used to sterilize the seed can have a profound impact on transformation efficiency. Paz *et al.* (2004) found that batches of seed from different suppliers produced seedlings that varied in their response to tissue culture conditions. These researchers also reported that the time used for sterilizing seed with chlorine gas could impact rates of transformation.

Of particular importance and difficult to relate in print is the technique used to wound the cot-node tissue prior to incubation with *Agrobacterium*. Precise wounding at the correct position at the cot-node junction is critical, but producing the correct wound in a consistent manner is very difficult. To overcome certain limitations associated with the cot-node system,

Paz *et al.* (2006) developed a new method that employs cotyledons derived from seed imbibed overnight as opposed to cotyledons derived from seedlings in the traditional cot-node process. This method eliminated the need for precise mechanical wounding, apparently because the wound produced from removal of the embryo axis was sufficient to permit access to meristematic target tissue by *Agrobacterium*. Rates of transformation using this split seed approach were about 50% higher than the rates observed using the more traditional cot-node system. However, only about 3% of the treated explants gave rise to transgenic plants.

Other organogenic tissue culture systems are being developed and could be useful as targets for transformation. Adventitious shoots can be formed from hypocotyl explants on media containing appropriate levels of BA (Dan and Reichert, 1998). Franklin *et al.* (2004) found that the cytokinins 6-benzylaminopurine (BAP) and thidiazuron (TDZ) act synergistically to induce organogenic nodules and shoot buds from both mature and immature cotyledons. Shan *et al.* (2005) also used TDZ to successfully produce multiple bud tissue from cotyledons. These buds can be proliferated and maintained for extended periods in tissue culture, suggesting that the bud cultures can be suitable targets for transformation.

2.1.2 Transformation using somatic embryogenesis

Another tissue culture approach is to induce a process termed somatic embryogenesis. Somatic embryogenesis involves the development of embryolike structures from vegetative (nongametic) cells. For soybean, somatic embryogenesis is most often induced by placing immature cotyledons on medium containing an auxin, usually 2,4-D (Ranch *et al.*, 1985). Clusters of globular stage somatic embryos can be excised from cotyledons, placed in liquid proliferation medium from which the cultures can be subcultured and expanded (Finer and Nagasawa, 1988). Regeneration is accomplished by transfer to media lacking auxin, histodifferentiation of mature somatic embryos, and a subsequent brief drying process that is necessary to permit germination. Recent advances in liquid maturation media have greatly simplified

the regeneration process (Walker and Parrott, 2001; Schmidt *et al.*, 2005). As is the case for the cot-node tissue culture system, the embryogenic response of soybean is also genotype dependent (Bailey *et al.*, 1993; Simmonds and Donaldson, 2000; Tomlin *et al.*, 2002).

Particle bombardment of embryogenic cultures is commonly used to produce transgenic soybean. In the first reported example (Finer and McMullen, 1991), embryogenic material was co-transformed with plasmids harboring the visual marker gene GUS, and the selectable marker gene AphIV, which detoxifies the antibiotic hygromycin. Clumps of embryogenic tissue were bombarded with DNA-coated particles. Following DNA delivery, the tissue was cultured in liquid medium supplemented with 50 mg l⁻¹ hygromycin for 6–8 weeks with media changed at regular intervals. One or two small yellowish-green clusters of hygromycin-resistant tissue were recovered from each bombardment experiment. The surviving tissue was removed from selection and allowed to grow for an additional 3–4 months. The subsequent differentiation, maturation, desiccation, and germination steps were conducted without further selection. The first attempts to transform these embryogenic cultures proved successful but were hampered by low efficiency and frequent recovery of infertile plants. Others have noted low rates of transformation and poor regeneration frequency of plants from transgenic cultures (Parrott *et al.*, 1994; Droste *et al.*, 2002), averaging less than one event per bombarded sample, while other researchers report more efficient levels of transformation (Sato *et al.*, 1993; Simmonds and Donaldson, 2000). Poor rates of transformation and regeneration may be due to the long periods of time in tissue culture needed to produce cultures capable of transformation (Singh *et al.*, 1988). Optimizing levels of nitrogen and sucrose in the liquid proliferation medium could enhance growth and morphology of embryogenic cultures (Samoylov *et al.*, 1998). Since transformation is tied to the accessibility of mitotic cells (Hazel *et al.*, 1998), cultures derived from the optimized medium should be more readily amenable to transformation than those maintained in the original medium developed by Finer and Nagasawa (1988). Bombarding embryogenic cultures at a specific time after subculture may enhance rates of transformation (Hazel *et al.*, 1998). This is

related to a burst of cell division that peaks about 5 days after subculture. Different cell cultures derived from the same genotype can develop distinct morphologies during repeated subcultures, with some cultures having a denser arrangement of globular structures and capable of supporting higher rates of transformation. These morphologies can also be related to the number of cells undergoing division in the outer layers of the tissue. Other treatments can be used to enhance rates of stable transformation. For example, Vain *et al.* (1993) found that pretreatments that decrease the turgor pressure of embryonic tissue can increase rates of transformation.

Agrobacterium has also been used to deliver genes to embryogenic culture but with limited success. Trick and Finer (1998) utilized sonication to wound embryogenic suspensions. Following co-cultivation with an *Agrobacterium* strain carrying a hygromycin resistance gene, a large number of transgenic cell lines were recovered. Plants regenerated from these events were infertile, probably because of the extended age of the cultures. Droste *et al.* (2000) used a combined particle bombardment and *Agrobacterium* technique for transformation of embryogenic suspensions, but did not report plant recovery.

Particle bombardment or *Agrobacterium* can be used to deliver genes directly into immature cotyledons with subsequent recovery of transgenic somatic embryos. Parrott *et al.* (1989) recovered several transgenic events from immature cotyledons treated with *Agrobacterium*. Yan *et al.* (2000) also found extremely low rates of transformation of cotyledon explants with only 0.03% of treated cotyledons giving rise to transgenic plants. In a series of publications, Ko *et al.* (2003, 2004; Ko and Korban, 2004) optimized various parameters including the size and orientation of the cotyledon, *Agrobacterium* strain and concentration, time of co-cultivation and hygromycin concentration to achieve relatively high rates of transformation. About half of the cotyledons treated with the hyper-virulent strain of *Agrobacterium*, KYRT1, formed embryogenic clusters resistant to hygromycin. Lim *et al.* (2005) extended this work and found that expression of a soybean mosaic virus helper component-protease (Hc-Pro) enhances rates of transformation and stabilizes transgene expression in resulting transformants. Hc-Pro acts as a suppressor of post-transcriptional gene

silencing. It is known that transgenes can be silenced soon after transfer to plant cells (Johansen and Carrington, 2001). Apparently, Hc-Pro acted to prevent silencing of the introduced hygromycin-resistance gene, leading to a 2.4-fold increase in transformation rates.

2.1.3 Gene transfer to apical meristems and other approaches with minimal tissue culture

As is evident from the above discussion, transformation methods for soybean are often dependent on proliferating and maintaining tissue in culture and most laboratories practicing soybean transformation rely on these approaches. Transformation technologies that minimize or eliminate tissue culture can potentially reduce time and labor requirements. Gene delivery to apical meristems or to seed or seedlings has been used in developing effective transformation systems for a number of species. For example, *Arabidopsis* can be transformed by simply inoculating flowers with an *Agrobacterium* suspension. A small proportion of seed from these plants is transgenic (Desfeux *et al.*, 2000). A similar system for soybean would be of great utility. De Ronde *et al.* (2001a) attempted to develop a soybean transformation system based on the *Agrobacterium* infiltration method used for *Arabidopsis*. These authors claimed that 30% of the seed from the *Agrobacterium*-treated plants were transgenic, however, replicated results have not yet been published. Hu and Wang (1999) summarized research concerning soybean transformation by techniques using direct injection of DNA into ovaries or by application to pollen tubes. However, this result has not been reproduced and attempts to produce transgenics by floral tube pathway have been unsuccessful (Li *et al.*, 2002).

Agrobacterium has also been used to transfer DNA directly into meristematic cells within the shoot apex, minimizing tissue culture steps. Chee *et al.* (1989) inoculated the area around the apex by inoculating the plumule, cotyledonary node, and adjacent cotyledon tissues of germinating seed. Seedlings were screened for the presence of the transgene by an enzyme assay for NPTII activity. About 0.07% of the recovered plants were transgenic and transformation was confirmed by Southern blot in both primary transformants

and progeny. Although transformation frequencies were extremely low, the study showed that tissue culture is not always necessary for transformation. Efendi *et al.* (2000) carried out similar experiments with NPTII, hygromycin phosphotransferase (HPT), and GUS genes.

Liu *et al.* (2004) also utilized apical meristems as targets for transformation. Meristems were excised from imbibed seed, co-cultivated in an *Agrobacterium* suspension, and placed on a medium containing hormones that promote rapid proliferation of multiple shoots. Relatively high rates of transformation were noted, matching those reported by Olhoft *et al.* (2003). A relatively long co-cultivation period of 20 h was determined to be important for success of this technique.

Particle bombardment can also be used to deliver genes directly to cells within the apical meristem (McCabe *et al.*, 1988). These researchers developed a custom designed gene gun that utilized capacitance discharge between two electrodes to produce a shock wave. This shock wave provided the force necessary to accelerate a mylar sheet, whose front surface was coated with DNA-bearing particles, into a metal screen. The screen stopped the mylar sheet and allowed the passage of the accelerated particles into the target tissue. Following bombardment the meristems were placed on medium that induces multiple shoot formation. The cultures were then maintained until shoots from either the primary or axillary meristem reached 0.5–1.0 cm in length. This tissue culture regime permits the formation of 5–10 shoots from each bombarded meristem. The visual marker gene, GUS, was used to screen for transgenic plantlets arising from bombarded meristems (Christou *et al.*, 1989). Not all GUS-expressing shoots transmitted the transgene to the next generation. In this first report, only one shoot from about 400 that were sampled expressed GUS activity in both the primary and second-generation plants. Many plants exhibited sectors of GUS expression, but not all of these sectors encompassed a cell lineage that gave rise to a gamete (Christou and McCabe, 1992). After observing a series of GUS-expressing shoots, these researchers were able to identify GUS expression patterns that could be used to predict the likelihood of inheritance of the transgene in the next generation. Plants with GUS sectors in the stem that extended from the epidermis through

the cortex and pith usually produced seed carrying the transgene. This system has the advantage of minimal *in vitro* culture time, thus limiting the probability of generating mutations during tissue culture. The applicability of this system to a number of commercially important genotypes was also demonstrated. However, the system is very inefficient and labor intensive.

Aragao *et al.* (2000) employed a similar bombardment system for transformation of apical meristems, delivering a gene that provides tolerance to imidazolinone herbicides. By generating shoots from bombarded meristems on medium containing imazapyr, these researchers were able to use selection to enhance recovery of transgenic shoots from bombarded meristems. These researchers reported that up to 7% of the regenerated shoots were transgenic and transmitted the transgene to the next generation.

2.1.4 Nature of transgenic loci

Knowledge of the number and structure of transgenes in the host genome is important for subsequent analysis of function and phenotype. The presence of multiple transgene copies can lead to unpredictable levels of gene expression and inheritance of phenotype (Meza *et al.*, 2001; De Buck *et al.*, 2004; Schubert *et al.*, 2004). *Agrobacterium* was once thought to produce transgenic loci with very simple insertions of DNA, often consisting of single copies lacking sequence from the plasmid backbone. However, Olhoft *et al.* (2004) found that 37% of soybean transformants recovered from the cotyledonary node system harbored vector backbone. *Agrobacterium*-derived transformants also often harbor multiple copies of the transgene. Olhoft *et al.* (2003) conducted molecular characterization on 72 individual lines of transgenic soybean derived from *Agrobacterium*-mediated transformation. The data revealed that of the 72 lines, 29 (40%) possessed hybridization patterns suggestive of complex T-DNA integration. The majority (48%) of the transgenic lines analyzed transmitted the transgenes as a single functional locus. Thus, complex loci containing multiple copies of the transgene can be inherited as a single locus. Olhoft *et al.* (2004) conducted detailed analysis of 270 independent transgenic plants. Only about 30% of these had single copies of

the transgene cassette. A significant proportion (about 30%) of the transgene insertions was truncated.

Particle bombardment can also produce transgenics with complex transgene integrations, and the gene of interest must be physically purified from the vector backbone by electrophoresis to avoid its delivery into the host genome. The introduction of vector backbone DNA can be circumvented by coating particles with linearized DNA elements that only contain the gene(s) of interest. Transgenic rice produced by bombardment with these linearized gene cassettes had very simple patterns of transgene insertion (Fu *et al.*, 2000). In addition, merely reducing the amount of DNA delivered per shot can decrease insert complexity in microprojectile-derived soybean transformants and promote insertion of single transgene copies into the soybean genome (Simmonds, 2003).

2.2 Agronomic Input Traits

Soybean grain yield and quality are controlled by genetic elements and environmental factors that regulate the growth, development, and reproduction of soybean plants. Soybean scientists are applying biotechnology to prevent yield losses through transgenic control of pests, diseases, herbicides, and abiotic stress. In this section, we will discuss the improvements of agronomic input traits including excellent examples of how biotechnology and transgenic breeding benefit soybean grain production.

2.2.1 Nematode resistance

Over 100 species of nematodes can infect soybeans. All of them are soil dwelling and live in or on the soybean roots. Among the soybean nematode parasites, SCN, *Heterodera glycines*, is the most destructive soybean pathogen worldwide, causing billions of dollars in yield loss worldwide each year. Some of the root-knot nematodes (RKNs), *Meloidogyne* spp., are important problems in southern America (Niblack *et al.*, 2004). The SCN population has been separated into 16 different races or homogenistic (HG) types (Niblack *et al.*, 2002) based on their ability to infect different soybean lines. During infection, soybean roots are

damaged by nematodes causing symptoms, such as retarded growth, wilting, low seed yield, and altered root morphology.

Second-stage juveniles (J2) are the infective stage of the nematodes, which penetrate the soybean roots. Once inside the roots, the J2 secrete many compounds, which transform a group of root cells to form a specialized feeding structure, known as a syncytium (SCN) or giant cell (RKN). The feeding structure is the only channel through which nematodes can ingest nutrients from the soybean cells, and is therefore imperative for nematode growth and reproduction. The nematode accesses the feeding structure by piercing the cell with a hollow stylet. A feeding tube leads the nutrients to the stylet and into the nematode (Davis *et al.*, 2004). Current nematode control relies on the use of resistant soybean varieties, crop rotation, and nematicidal chemicals, which are hazardous to the environment. The use of resistant varieties is the most effective and economical strategy.

Natural SCN resistance genes (R genes) have been mapped with molecular markers (Webb *et al.*, 1995; Vierling *et al.*, 1996; Concibido *et al.*, 2004), and some of them have been cloned by map-based cloning methods (Jung *et al.*, 1998; Lightfoot and Meksem, 2002). Both *Rhg1* and *Rhg4* genes encode the typical NBS-LRR type of R gene, containing a transmembrane domain and a protein kinase domain similar to the rice *Xa21* gene. *Rhg1* is located on soybean linkage group G (Concibido *et al.*, 1997), whereas *Rhg4* is found on soybean linkage group A2 (Concibido *et al.*, 2004). *Rhg1* is the major R gene for SCN resistance; it is necessary but not sufficient for resistance against all known races. *Rhg4* is a partner of *Rhg1* for resistance against SCN race 3 (Meksem *et al.*, 2001). A sequence homolog of the sugar beet nematode resistance gene *Hs1* has been cloned (Jessen and Meyer, 2001). Resistance conferred by R genes is not durable due to race shifting in the field. CystX is a commercial line exhibiting resistance to several SCN races (<http://www.cystx.com>). However, resistant varieties in general show yield penalty when grown in the absence of SCN. In attempt to avoid this obstacle, transgenic approaches have been pursued in both academic and industrial sectors, allowing genes to be quickly introduced into susceptible elite lines. This method may also allow for stacking of different modes of resistance, i.e., transgenes with R genes (Gheyson

and Fenoll, 2002; Atkinson *et al.*, 2003), leading to more durable nematode tolerance.

Transgenic plants are most commonly used to evaluate the effects of transgenes. Soybean hairy roots, induced by *Agrobacterium rhizogenes* strain K599, have also become a useful tool for evaluating candidate SCN resistance genes. Narayanan *et al.* (1999) found that the nematode life cycle can be completed on hairy root cultures and that resistance phenotypes are conserved. The primary method of measuring SCN susceptibility or resistance is by counting the number of mature females that have developed on a given root sample. Because SCN cysts are so small and their coloring is similar to the root, counting can be cumbersome and inaccurate. Lu *et al.* (2005) invented a fluorescence imaging system that has greatly reduced the effort needed to count cysts. Fluorescence imaging improves accuracy by allowing the operator to visualize cysts that are small or obstructed from view. Another assay has been developed for evaluating double-stranded RNA (dsRNA)-induced silencing that involves inducing feeding in J2 with chemicals, such as octopamine or resorcinol, enabling nematodes to feed without the formation of a feeding site. This type of testing provides a quick way to introduce dsRNA molecules into the nematodes and conduct molecular analyses without the establishment of a nematode feeding site under *in vitro* conditions.

Several strategies toward engineered SCN resistance are being explored including expression of antinematode proteins (or peptides), blocking feeding site formation, and knocking off essential nematode genes. Proteinase inhibitors (PIs) are often part of a plant's wounding response. Because they are not toxic to the plant, they can be constitutively expressed, possibly leading to resistance to other soybean pests (Jung *et al.*, 1998). Urwin *et al.* (1997a) studied a mutated oryzacystatin-I gene from rice, *Oc-IAD86*, expressed in *Arabidopsis* plants. The *Oc-IAD86* gene was expressed under CaMV 35S promoter and Nos terminator (Table 3) in a binary vector, which was transformed into *Arabidopsis* by *Agrobacterium*-mediated transformation. Selected events contained a single copy of the *Oc-IAD86* gene, as confirmed by Southern blot analysis. Quantitative Western blot analysis revealed that the expression of *Oc-IAD86* was 0.4% of the total

protein. Ingestion of the modified cystatin from the plant was correlated with a loss of cysteine proteinase activity in the intestine, preventing female nematodes of both *Meloidogyne incognita* and *Heterodera schachtii* (beet-cyst nematode) from becoming large enough to produce eggs. Urwin *et al.* (1997b) also identified genes for two cysteine proteinases in *H. glycines*, hgcp-I and hgcp-II. The same engineered *Oc-IAD86* cystatin as described above was able to inhibit the activity of Hgcp-I, but not Hgcp-II in cryosections (Lilley *et al.*, 1996). Urwin *et al.* (1998) achieved resistance to *M. incognita* and *H. schachtii* in transgenic *Arabidopsis*. Translational fusion constructs containing the genes for PIs CpTI and *Oc-IAD86* joined by a noncleavable linker was generated by polymerase chain reaction (PCR). Individual *CpTI* and *Oc-IAD86* sequences, as well as the fused sequence, were driven by the pBI121 CaMV 35S promoter and Nos terminator (Table 3) for analysis in plants. The constructs were introduced into *Arabidopsis thaliana* via *Agrobacterium*-mediated root transformation. Expression analysis was conducted by Western blot using antibodies for both *Oc-IAD86* and *CpTI*. In both *Escherichia coli* and *Arabidopsis*, expression of the noncleavable construct resulted in a protein of ~23 kDa that contained both PIs. Relative-inhibition assays were also carried out to ensure that the proteins were still active in their various forms. Western blot analysis of *M. incognita* and *H. schachtii* females recovered from T₁ roots revealed that the nematodes had ingested *Oc-IAD86* or *CpTI* when recovered from plants expressing single PI constructs. The 23 kDa fusion proteins were detected in *M. incognita*, but not in *H. schachtii*. Results of infection assays showed that expression of *CpTI* in either form changed the *H. schachtii* sex ratio, evident by the reduced number of saccate females at 20 dpi on T₁ plants. At 45 dpi fewer mature females were observed on the *CpTI*-transformed roots than on the controls. Plants expressing *Oc-IAD86* or the fusion protein had a greater number of females with delayed development compared to the controls. The data showed that the expression of the two proteins fused together had an additive effect that can confer resistance to the RKN. The data also indicate that *M. incognita* is able to take up proteins up to 23 kDa, despite the small opening in the stylet. Although there is no direct evidence yet,

^(a)NA, not available

these PIs may also confer resistance in soybean for both SCN and RKN.

A relatively new approach to nematode resistance is RNA interference (RNAi). This phenomenon was first identified by Guo and Kemphues (1995) and subsequently by Fire *et al.* (1998) in *Caenorhabditis elegans*. Urwin *et al.* (2002) used a J2 forced feeding assay to investigate cysteine proteinase gene silencing in *H. glycines* and *G. pallida*. Reduced transcript abundance was evident; however, subsequent infection did not lead to a reduction in the number of parasites, but resulted in a shift from the normal male/female ratio of 75% to 50% after RNAi. Forced feeding SCN J2 with C-type lectin dsRNA was found to reduce SCN reproduction on roots by 41% (Urwin *et al.*, 2002). RNA soaking assays with RKN revealed that the dual oxidase gene (Bakhetia *et al.*, 2005a), polyglacturonase gene, calreticulin gene, (Rosso *et al.*, 2005), and chitin synthase gene (Fanelli *et al.*, 2004) are all important genes for RKN development and reproduction. These genes are potential candidates for engineering soybean for SCN and RKN resistance through the RNAi approach (Bakhetia *et al.*, 2005b).

Expression of nematode dsRNA in plants has already been demonstrated. In order to obtain deleterious effects on the nematode *in planta*, SCN-specific dsRNA I is expressed in the syncytium. The nematode is then able to draw the dsRNA into the gut cells and RNA silencing is induced. Trick *et al.* (2004) and Steeves *et al.* (2006) expressed dsRNA corresponding to the nematode major sperm protein (MSP) gene in soybean plants. Degenerate primers were used to amplify a *MSP* gene fragment from *H. glycines* genomic DNA. The fragment was then used to isolate the *MSP* complementary DNA (cDNA) from a *H. glycines* J2 juvenile cDNA library. Approximately 250 bp sense and antisense sequences of the *MSP* cDNA were linked by a loop of ~112 bp. The fragment was flanked by the *Arabidopsis* actin-2 promoter (An *et al.*, 1996) and terminator for transformation. Particle bombardment was used to transform soybean somatic embryos with the hairpin construct. The resulting transgenic plants were confirmed by hygromycin selection and subjected to bioassay testing. The first greenhouse bioassay was used to determine SCN resistance in the transgenic plants. Events were transplanted into SCN-infested soil and after 6 weeks, the

number of cysts, eggs per cyst, and root weight data were recorded. Cysts from replicates of each event in the first experiment were pooled independently and eggs were collected. The eggs were then used to inoculate Flyer plants (a soybean line with no resistance to SCN) in sterile soil. After growing in the infected soil for 6 weeks, data on cyst number, eggs per cyst, and root weight were collected. The number of cysts per plant was slightly reduced in the transgenic line compared to the nonengineered control during the first bioassay. Results of the second bioassay revealed that a much higher reduction occurred in the second generation of cysts exposed to the *MSP* RNAi. The effects of the *MSP* transgene were present in the first generation and may have been carried over into the second generation. Bioassay 1 had a 64% reduction in the number of *H. glycines* eggs per plant. In the second experiment, even though the eggs from the transgenic and nontransgenic control lines were applied at the same rate, the number of eggs per transgenic plant was significantly reduced (71%).

Ren *et al.* (2005) reported resistance to race 3 SCN in soybean hairy roots. Four SCN target genes were identified through GenBank SCN EST and *C. elegans* databases. Targets were checked for low homology to soybean genes at the DNA sequence level. Fragments of *H. glycines* homologs to *C. elegans* genes were isolated from cDNA for each of the targets: *cct-6* (545 bp), *daf-21* (399 bp), *Y65BR.5a* (499 bp), and *pat-10* (399 bp). In order to validate the targets, a nematode soaking assay was conducted. dsRNA was amplified by T7 *in vitro* transcription for the four targets and a GUS control. Freshly hatched SCN J2s were soaked in a 0.6 mg ml⁻¹ dsRNA solution for 5 days. Observation of nematode mobility versus immobility was assessed in order to determine efficacy of the targets. In a representative experiment, 95% of the J2 soaked in water and 60% of the J2 treated with GUS dsRNA exhibited active motility, showing that some nonspecific activity may be occurring. However, the activity of the targets was still evident above this high baseline. *H. glycines cct-6* showed the highest activity, immobilizing 90% of the nematodes. Similarly *daf-21* immobilized 75% and *Y65BR.5a* immobilized 80%. In another experiment, *pat-10* dsRNA immobilized 53% of the J2, compared to 8% and 26% in water- and GUS-treated samples, respectively. The targets

were also tested in a *C. elegans* feeding assay. After 5 days of feeding, the controls had advanced to gravid adults and produced a second generation, whereas the four targets resulted in developmental arrest. These data indicate that the selected targets play a key role in the development of both *C. elegans* and *H. glycines*. Ren *et al.* (2005) further evaluated the SCN target genes in soybean hairy roots. Sense and antisense fragments of the targets were linked together with an intron, encoding dsRNA. The transgene was driven by the SuperMas promoter (Ni *et al.*, 1995) that drives expression at a high level in many tissues including roots. Binary vectors of the individual targets were made, and then a vector containing three of the targets, *cct-6*, *daf-21*, and *Y65BR.5a* were linked together in order to produce dsRNAs simultaneously. The vectors were transformed into soybean hairy roots via *A. rhizogenes*. Positive transformants were identified using the arsenal herbicide resistance gene driven by the Actin-2 promoter (Table 3). Expression of sense and antisense *pat-10* and *cct-6* DNA was confirmed by PCR analysis. Northern blot analysis also confirmed siRNA expression in the hairy roots. The transgenic roots were subjected to SCN infection and the number of female cysts was determined. Roots derived from the *pat-10* vector showed a statistically significant 23–85% reduction in female cysts compared to the susceptible controls. At this time, data for the other three targets and the concatemer construct have not been published.

Hussey and Huang (2006) and Huang *et al.* (2006) were able to apply the RNAi technology to control root-RKNs in plants. A clone encoding a 43 amino acid secretory signaling peptide, designated *16D10*, was identified during random sequencing of a gland-cell specific library of *M. incognita*. The protein sequence has some similarity to the *Arabidopsis* CLV3-like proteins (Cock and McCormick, 2001) as well as a cAMP/cGMP-dependent protein kinase phosphorylation site. Transformation of *Arabidopsis* *clv3* mutants, however, showed that the 16D10 protein does not have *clv3*-like activity (Hussey and Huang, 2006). Southern blot analysis showed that this clone is present in four agriculturally important species: *M. incognita*, *Meloidogyne javanica*, *Meloidogyne arenari*, and *Meloidogyne hapla*. *In situ* messenger RNA (mRNA) hybridization revealed that *16D10*

was strongly expressed in the two subventral esophageal gland cells of *M. incognita* at early parasitic stages. Stylet secretions were collected and found to contain the 16D10 peptide. An *M. incognita* J2 forced feeding assay was used to test the effect of 16D10 dsRNA. After 4 h of feeding, the J2 were subjected to RNA isolation and real time (RT) PCR. A significant reduction in the nematode *16D10* transcripts in the treated nematodes was observed providing direct evidence for targeting *16D10* in RKN. Binary constructs were prepared containing CaMV 35S promoter driving the hairpin containing *16D10* sense and antisense cDNAs linked together by an intron, followed by the Nos terminator (Table 3). This construct was transformed into *A. thaliana* via floral dip transformation. Transgenic plants were selected by kanamycin, and T₂ events were developed for nematode infection assays. The assays clearly demonstrated that the *16D10* RNAi plants are resistant to the four major *Meloidogyne* species. These plants showed a 63–90% reduction in the number and size of galls, and a 70–97% reduction in the number of RKN eggs per gram of root compared to the vector-transformed control plants. Considering these data, the *16D10* gene is a potent candidate for engineering RKN resistance in soybean.

2.2.2 Fungal resistance

More than 40 fungal pathogens are reported to cause significant plant disease worldwide (Hartman *et al.*, 1999), some of which infect soybean. The importance of the soybean diseases is dependent on the plant tissue type, environmental condition, and soybean genotype. Fungal pathogens can cause damage in seedlings, roots, stems, leaves, and pods (Grau *et al.*, 2004). The important fungal diseases include *Phytophthora* root and stem rot, sudden death syndrome (SDS), brown stem rot, *Fusarium* wilt, anthracnose, *Sclerotinia* diseases (white mold and *Sclerotinia* blight), powdery mildew, stem canker, frog-eye leaf spot, and soybean rust. Grau *et al.* (2004) described the symptoms, importance, and management for these diseases.

The *Phytophthora* diseases are caused by the oomycete *P. sojae*. These diseases cause severe destruction in soybean crops worldwide. This

pathogen can infect root and stem tissues and the infection rates are dependent on the environmental conditions. The interactions between the pathogen and its hosts have been reviewed recently (Tyler, 2002; Ellis *et al.*, 2006). The genome sequence of *P. sojae* is now available (<http://www.pfgd.org>). Native *Phytophthora* R genes (*Rps*) have been identified and isolated (Gao *et al.*, 2005). Resistant varieties are available and even new cultivars containing major resistance genes can show resilience to *P. sojae* for 5–10 years. Breeders are bringing several QTLs together into new varieties to build more durable resistance (Ellis *et al.*, 2006). Among these R genes, *Rps1-k* is the most stable and widely used. Four coiled coil-nucleotide binding-leucine rich repeat (CC-NB-LRR)-type proteins were isolated from the *Rps1-k* locus, and three of them have identical open reading frames and 5' end regions. These genes were designated *Rps1-k-1*, *Rps1-k-2*, *Rps1-k-3*, and *Rps1-k-4* and were transformed into transgenic soybean plants using their own promoters and terminators (Table 3) (Gao *et al.*, 2005). Transgenic plants were generated by *Agrobacterium*-mediated transformation and tested for four generations. The results consistently showed that expression of these R genes conferred enhanced resistance to *Phytophthora* in the transgenic soybean plants.

Sclerotinia sclerotiorum (Lib.) de Barry causes stem rot, also known as white mold, and is also an important soybean pathogen. The fungus colonizes dead tissue on the plant and then invades the host plant when wet soil and canopy conditions at flowering occur (Grau, 1988). Under suitable conditions, *Sclerotinia* initially infects soybean plants by way of ascospores that land on flowers. When moisture is adequate, the ascospores germinate and form mycelium, using the flower petals as a nutrient base. The pathogen causes lesions that completely encircle the stem and disrupt the transport of water, mineral nutrients, and photosynthates to developing pods. Cottony mycelial growth on all diseased plant parts is a characteristic sign of the pathogen. *Sclerotinia* can form inside and outside the infected tissues. Combating this problem with traditional technologies is difficult because few genetic sources of resistance are available. *Sclerotinia* resistance has been shown to be a quantitative trait (Gentzbittel *et al.*, 1998; Zhao and Meng, 2003); however, commercial germplasm has limited

genetic variation for resistance (Cober *et al.*, 2003; Hu and Lu, 2005). Kim and Diers (2000) and Arahana *et al.* (2001) identified several of the QTLs associated with resistance, though they were often associated with avoidance traits rather than physiological resistance. Low correlation between field and laboratory tests also contributes to difficulties in breeding (Boland and Hall, 1987; Wegulo *et al.*, 1998). Management of this disease includes utilization of crop rotation and chemical treatments, but these are expensive and often unsuccessful. Research on *S. sclerotiorum* pathogenicity factors has been the most promising lead toward transgenic resistance. As the fungus infects the host tissue, *Sclerotinia* secretions trigger a complex exchange of molecular signals and responses between the pathogen and its host. *S. sclerotiorum* secretes millimolar concentrations of oxalic acid into infected host tissues (Maxwell and Lumsden, 1970; Marciano *et al.*, 1983; Godoy *et al.*, 1990), acidifying the plant tissue and chelating the Ca^{++} from the cell wall, leaving the tissue susceptible to further breakdown by the fungus (Lumsden, 1979). Oxalic acid (OA) also inhibits *O*-diphenol oxidase (Ferrar and Walker, 1993), which suppresses the oxidative burst (Cessna *et al.*, 2000). Manual injection of oxalate into plants caused the development of *Sclerotinia* diseaselike symptoms (Bateman and Beer, 1965; Noyes and Hancock, 1981). Mutants of *S. sclerotiorum* that are deficient in the ability to synthesize oxalate are nonpathogenic, whereas revertant strains that regain their oxalate biosynthetic capacity exhibit normal virulence (Godoy *et al.*, 1990). The data clearly demonstrate that OA is a pathogenicity factor, and a common strategy is to degrade OA by expressing oxalate-degrading enzymes in plants for combating this fungal pathogen.

Donaldson *et al.* (2001) demonstrated that the wheat germin protein, oxalate oxidase (OXO), degrades oxalic acid and confers resistance to *Sclerotinia* in growth chamber inoculation tests. *Agrobacterium tumefaciens* was used to transform a binary vector containing a fragment of the wheat genomic clone *gf-2.8*, including its signal peptide sequence (Dratewka-Kos *et al.*, 1989; Lane *et al.*, 1991); linked to the CaMV 35S enhanced promoter (Odell *et al.*, 1985; Kay *et al.*, 1987) and the 3' terminator region from pFF19 (Table 3). Kanamycin resistance was used to select transgenic shoots. Expression was confirmed

through an OXO histological assay, and was detected in all tested tissues. Western blots showed that the transgenic soybeans expressed a 130 kDa protein similar to the native germin. Line 80-30-1, which was selected for further investigation of *Sclerotinia* resistance, was positive for OXO activity, but negative for the marker gene. Progeny of this line have shown stable transmission of the OXO transgene up to the T₈ generation. Events from the homozygous T₃ generation were tested for *Sclerotinia* resistance in growth chamber assays by cotyledon and stem inoculation. Both assays consistently showed that the transgenic line exhibited a higher level of resistance to *Sclerotinia* infection and higher survival rate when compared to the null and parental lines. During the cotyledon infection assays, *Sclerotinia* lesions on the controls and transgenics extended similarly, however when the lesion reached the hypocotyl, infection stopped and the plants were able to recover. Stem inoculations revealed a delayed infection, significantly reducing the lesion size. Field studies to characterize the 80(30)-1 transgenic soybean line described above were conducted by Cober *et al.* (2003). The study was completed over 3 years at three different sites. Infected plants were rated for disease severity index (DSI) at the beginning of leaf senescence (0 = no infection; 100 = all plants killed by white mold). Results showed that the transgenic line was significantly less infected with *Sclerotinia* than the negative sib line. At one site, plants were artificially infested with *S. sclerotiorum* sclerotia. The transgenic line had an average DSI of 7 while the negative sib line had an average DSI of 46 across the 3-year period. Two resistant cultivars, Maple Arrow and OAC Salem, had a DSI of 2 over 2 years. The OXO transgene was not able to confer complete resistance to white mold infection; however, in a susceptible genetic background its resistance level was quite comparable to the current resistant short-season cultivars.

Sclerotinia blight in soybean, also known as southern blight, occurs primarily in southern America. This is a soybean-specific disease caused by *Sclerotinia rolfisii*, which produces oxalic acid as the major pathogenic factor (Bateman and Beer, 1965). Livingstone *et al.* (2005) reported that overexpression of barley OXO conferred enhanced resistance to *Sclerotinia* blight in peanut, which is caused by *Sclerotinia minor*. Both *S. minor* and

S. rolfisii produce oxalic acids. Direct application of oxalic acid to stem or leaf tissue causes tissue injury and wilting in soybean, similar to plant responses to fungal infection by *S. rolfisii* (Bateman and Beer, 1965) and *S. sclerotiorum* (Noyes and Hancock, 1981). Therefore, oxalate-degrading enzymes may also confer enhanced resistance to soybean *Sclerotinia* blight. However, OXO is a potential allergen as indicated by the results from Jensen-Jarolim *et al.* (2002). In addition to OXO, there are two other classes of oxalate degrading enzymes, oxalate decarboxylase and oxalyl-CoA-decarboxylase, which also have potential for engineering *Sclerotinia* resistance (Lu, 2003; Hu and Lu, 2005; Lu and Hoeft, 2008).

Gene flow has been reported and is a concern for transgenic crops such as sunflower (Snow *et al.*, 2003). To address this issue, Burke and Rieseberg (2003) backcrossed the OXO transgene from OXO-sunflowers to wild species and carried out case and field experiments using the progeny. The OXO transgene was shown to enhance resistance to *S. sclerotiorum*, but did not significantly impact seed production and reproductive fecundity of the wild species. These results indicate that genetically enhanced wild plants will not become more “weedy” since they do not produce more seeds than unmodified controls (Lu and Hoeft, 2008). In addition, there are no wild relatives of soybean in the United States and soybeans are self-pollinated crop, therefore if a transgene were released in these areas, no comparable weeds or wild relatives would be receptive to the gene through pollination, eliminating the risk of gene flow in the United States. This is a big advantage for developing transgenic soybean products.

Asian soybean rust, caused by *Phakopsora pachyrhiz* or *Phakopsora meibomia*, was first observed in Japan in 1902 and was found throughout most Asian countries and Australia by 1934. Rust was identified in South America in 2001, and the first US cases were discovered in November 2004. Currently, there are no commercial US soybean cultivars that are known to be resistant to soybean rust. Annual losses in future years could average \$240 million to \$2 billion worldwide, depending on the severity and extent of outbreaks (www.ers.usda.gov). Current fungicides and tolerant varieties as well as crop rotation are the main means of controlling the rust disease (McGinnis and Suszkiw, 2006).

Glyphosate was proposed to inhibit rust disease in the Roundup Ready-soybean fields (Feng *et al.*, 2005). The technology developed while studying other diseases in soybean and other crops (Gurr and Rushton, 2005) may help to create a transgenic strategy for the control of rust and other diseases.

No transgenic crops with enhanced fungal disease resistance are available or even close to being commercialized yet (Castle *et al.*, 2006). However, several potential approaches are emerging for disease control (Hammond-Kosack and Parker, 2003; Narayanan *et al.*, 2004; Gurr and Rushton, 2005). One of the approaches is to express antifungal proteins (or peptides) for combating fungal diseases. Li *et al.* (2004) transformed genes encoding chitinase and ribosome-inactivating protein into transgenic soybean plants. The expression of both genes was confirmed in the transgenic lines. However, there is no further report of the effects of these antifungal proteins against fungal pathogens.

2.2.3 Virus resistance

There are more than 100 viruses capable of infecting crops. Soybean mosaic virus, bean pod mottle virus (BPMV), and soybean dwarf virus (SbDV) are the most important viruses affecting soybean (Conner *et al.*, 2004).

SbDV severely decreases the soybean yield by damaging the leaves and greatly reducing the number of seed pods. The virus is commonly found in Australia, Japan, and New Zealand. It can only transfer from plant to plant by female aphids. Plants infected with SbDV grow only to one-third of the normal size, and leaves become dark green and curl downward. Tougou *et al.* (2006) were the first to report transgenic resistance to SbDV conferred by RNA-induced post-transcriptional gene silencing. A transformation cassette was developed using sense and antisense orientations of the SbDV *CP* gene separated by a 670 bp loop of *GUS* gene sequence. The hairpin was flanked by the CaMV 35S promoter and Nos terminator (Table 3), and the HPT gene was used as a selectable marker. Both *CP* hairpin and hygromycin whole plasmid constructs were transformed into Jack by particle bombardment. One plant showing hygromycin resistance survived to produce T₁ seeds. PCR and Southern blot

analyses were used to confirm integration of the transgene. Of the T₁ plants, 68% showed the presence of the *CP* gene. Fragments representing the intact hairpin construct were also detected by Southern blot analysis of three T₁ plants; however, the same three plants did not have SbDV-*CP* expression as confirmed by Northern blot analysis. T₂ plants were tested against SbDV infection. Three out of seven plants showed no symptoms of infection compared to one out of seven in the control. Northern analysis showed that all seven of the tested T₂ plants had siRNA accumulation. When tested for virus accumulation, only the three without symptoms lacked SbDV-specific RNAs. These three events were considered to be resistant to SbDV and may be further evaluated for conferring SbDV-resistance in soybean lines.

BPMV commonly infects fields in the southern regions of the United States, however, in recent years infection has spread to northern regions as well. BPMV is a member of the genus comovirus, and is spread by many species of leaf-feeding beetles. The virus not only decreases seed yield, but also causes the seeds that form to be predisposed to other infection (Stuckey *et al.*, 1982). Reddy *et al.* (2001) was able to confer resistance in transgenic soybean expressing the BPMV pCP (coat protein precursor) gene. The BPMV-*pCP* gene was removed from pMON1900 (Di *et al.*, 1996) and inserted into a bluescript-based plasmid containing a duplicated Figwort mosaic virus (FMV) 35S promoter and *rbcs* terminator (Table 3). This construct was then ligated into binary vector pHIG (Yan *et al.*, 2000). Somatic embryos of Jack were transformed by particle gun bombardment. Transformed material was selected by growing embryos on media containing hygromycin. Ninety-five percent of the events showed integration of the hairpin transgene (confirmed by Southern blot analysis). Probing Northern blots with the loop region of the hairpin revealed the presence of the transcript in all plants. GUS staining was also used to confirm presence of the transcript. Expression levels of the 63 kDa pCP were estimated by enzyme-linked immunosorbent assay (ELISA) to be as high as 0.2% of the total soluble protein in the leaves. Detached leaves of the primary transformants showed lower levels of BPMV accumulation compared to the nontransformed control. T₁ and T₂ plants were subjected to rub-in inoculation

with a purified preparation of Hopkins, the severe strain of BPMV. All inoculated plants inheriting the *pCP* gene are resistant to BPMV. Use of this gene in soybean lines may help to alleviate some of the viral problems occurring in fields today. RNAi technology may play important roles in engineering broad-spectrum virus control (Prins, 2003). In addition, BPMV can be used as a vector for expression of recombinant proteins in soybean, and a viral vector for gene silencing (Zhang and Ghabrial, 2006).

2.2.4 Insect resistance

Many insect species have been reported to infect soybean (Kogan and Turnipseed, 1987). These insects can be classified into three groups by the tissues they target. These include pod, stem, and seed feeders; foliage feeders; and root and nodule feeders. The important soybean insects include southern green stink bug, bean leaf beetle, corn earworm, soybean looper, grasshopper, soybean aphids, and soybean nodule fly. Boethel (2004) has reviewed soybean insects and insect management.

Bacillus thuringiensis (*Bt*) is a soil bacterium that produces insecticidal crystalline proteins. Insoluble crystalline proteins, also known as δ -endotoxins, are produced during sporulation. The *Bt* crystalline proteins kill the insect by binding to a receptor on the epithelial brush border membrane of the midgut, causing a disruption of osmotic balance, and leading to cell lysis. More than 50 toxin genes have been cloned from *Bt* (Zhu *et al.*, 1999). *Bt* is currently the most effective strategy for insect resistance in soybean and other crops (Castle *et al.*, 2006). Mazier *et al.* (1997) summarized the expression of δ -endotoxin genes from *Bt* in plants including soybean. Parrott *et al.* (1994) first reported successful transformation of a native *cryIAb* gene in soybean plants. This gene was isolated from *Bt* var. *Kurstaki* HD-1 and is specific for soybean and cabbage loopers. The promoter used for expression of *cryIAb* is the CaMV 35S promoter and the polyadenylation and leader sequences of alfalfa mosaic virus Orf25 were used as terminator (Table 3) and 5'UTR enhancer, respectively. This construct was transformed into soybean by particle bombardment of embryogenic cultures, and the transformants were selected on hygromycin. Mature somatic embryos were

recovered from hygromycin-resistant cell lines, and were converted into plants. Transgenic plants were further confirmed by Southern blot and hygromycin resistance analysis. A T_0 leaf-feeding assay indicated that overexpression of the *cryIAb* gene in the soybean lines conferred resistance to velvetbean caterpillar feeding, development, and survival at a level comparable to the traditional insect resistant line GatIR81-296. The resistance was correlated to the expression level of the *cryIAb* gene in the transgenic soybeans.

Stewart *et al.* (1996) transformed a synthetic *Bt* gene, designated *cryIAc*, into soybean cv. Jack for engineering insect resistance. The truncated *cryIAc* gene was originally isolated from *Bt* var. *Kurstaki* and was synthesized based on the methods described by Adang *et al.* (1993). The modified *cryIA* gene has the codon usage pattern of an average dicot gene and does not contain AT-rich nucleotide sequences typical of native *Bt* *cry* genes. The CaMV 35S promoter and Orf25 terminator (Table 3) (Murray *et al.*, 1991) were used to express the *cryIAc* gene. This construct was transformed into somatic embryos of Jack using particle bombardment. Approximately 10 g of tissue were bombarded, and three transgenic lines were identified by hygromycin selection. Fertile transgenic soybean plants were regenerated from the transgenic tissues. One of the lines was confirmed to accumulate *cryIAc* protein up to 46 ng mg⁻¹ soluble protein. In leaf-feeding bioassays, the transgenic plant leaves showed resistance to damage by corn earworm, soybean looper, velvetbean caterpillar, and tobacco budworm. The insect resistance level of these transgenic plants is higher than that of the insect-resistant line GatIR81-296. In field studies, the *Bt*-Jack line showed threefold to fivefold less defoliation by corn earworm and eightfold to ninefold less defoliation from velvetbean caterpillar compared to the nontransformed Jack (Walker *et al.*, 2000). The *Bt*-Jack plants also showed relatively lower resistance to soybean looper and exhibited fourfold greater resistance than Jack to natural infestations of lesser cornstalk borer. The truncated *cryIAc* gene is very similar to the *Bt* gene used for transforming commercialized *Bt* cotton and corn plants (All *et al.*, 1999b). These results indicate that expression of this *cryIAc* gene in soybean can provide a significant level of resistance to several soybean pests (Walker

et al., 2000). Some soybean varieties are known to have native insect resistance (All *et al.*, 1999a). Walker *et al.* (2002) first reported a multiple resistance gene pyramiding strategy using MAS. The *cry1Ac* gene in Jack was crossed with native resistance lines, combining both modes of resistance into a single soybean line. Field trials were conducted to evaluate resistance to corn earworm and soybean looper, and detached leaf bioassays were used to test for resistance to *Bt*-resistant and *Bt*-susceptible strains of tobacco budworm. Transgenic lines with significantly more resistance to the lepidopteran pests were identified. Stacking the *Bt* gene with native resistance genes may enhance the resistance further and provide multiple modes of insect resistance.

Macrae *et al.* (2005) evaluated transgenic soybean lines expressing a synthetic *cry1A* gene (*tic107*) in screenhouse and conventional field trials. The *cry1A* gene was isolated from *Bt*. A synthetic *cry1A* construct similar to *cry1Ac* (Fischhoff and Perlak, 1995) was constructed and transformed into soybean line A5547 by *Agrobacterium* (Hinchey *et al.*, 1988). The *cry1A* gene was expressed under *Arabidopsis* Rubisco small subunit promoter (Table 3). The precursor protein was directed to the chloroplasts under the guidance of the N-terminal stromal-import sequence of *ArabSSU1A*. Three marker-free lines were identified by Southern blot analysis. Progeny from the three transgenic soybean lines were evaluated in greenhouse trials against velvetbean caterpillar and soybean looper in the United States and against velvetbean caterpillar, *Epinotia aporema* (Walsingham), *Rachiplusia nu* (Guenée), and *Spilosoma virginica* (F.) in Argentina. All transgenic soybeans containing the *cry1A* gene exhibited almost complete control against each of the lepidopteran pests. Transgenic plants from two of the lines demonstrated season-long high dose against *A. gemmatilis* and *P. includens* in both field and greenhouse assays. These lines have a single copy of the *cry1A* gene and no marker gene. The results clearly demonstrate that *cry1A* can confer highly efficacious control of several lepidopterans in soybeans. The *Bt* soybean line is under further characterization including field performance, yield performance, and efficacy confirmation. A regulatory approval application has been filed for commercial release.

The bean leaf beetle, *Cerotoma trifurcata* (Forster), is one of the most important soybean pests in the United States. This insect was once an infrequent soybean pest in the Midwest; however in the 1970s, soybean growers began reporting increased incidence of bean leaf beetle damage (Boethel, 2004). Since 2000, this pest has become a more important problem partly because it also acts as a vector for BPMV. The insect feeds on infected plants and transmits the virus particles to the next plant on which it feeds. Another important soybean insect is soybean aphid (*Aphis glycines*) (Marking, 2001). Soybean aphid is a leaf pest, which damages soybean plants by reducing photosynthesis and yield. The aphid transmits soybean mosaic virus (Boethel, 2004). Soybean plants can be infected simultaneously by the insect pests and the viruses, which causes even more plant damage. Currently insecticides are the main management for these pests (Boethel, 2004).

In addition to *Bt* genes, scientists have evaluated PIs for insect control in soybean and other crops (Ryan, 1990; Schultze *et al.*, 1998; Su *et al.*, 1999). Protein TcdA is an example of a non-*Bt* insecticidal protein (Liu *et al.*, 2003). This protein was isolated from *Photobacterium luminescens*, a soil nematode parasite. This gene was synthetically codon optimized according to dicot-preferred codon usage and expressed under constitutive CsVMV promoter (Verdaguer *et al.*, 1996) and Orf25 terminator (Baker *et al.*, 1983) (Table 3). The construct was transformed into *Arabidopsis* by *Agrobacterium*-mediated transformation and transgenic plants were identified by kanamycin selection. The *TcdA-Arabidopsis* plants showed significant resistance to a number of feeding insects including southern corn rootworm (*Diabrotica undecimpunctata howardi*). The insect resistance was maintained for at least five generations in the transgenic *Arabidopsis* plants. The *TcdA* gene could be a candidate for insect control in soybean. Other strategies against insects have been reviewed by Ferry *et al.* (2004).

2.2.5 Herbicide resistance

Herbicides are the primary means of weed control in soybean fields. Historically, weed control in soybean has relied on herbicides applied directly to the soil before weed emergence. Foliar-applied

herbicides have gained popularity more recently, which allow farmers to assess the nature of the weed infestation before treatment (Buhler and Hartzler, 2004). The first cases of resistance selection in soybean involved acetolactate synthase (ALS) inhibitor herbicides (Horak and Peterson, 1995; Sprague *et al.*, 1997), however, ALS-resistant weeds caused a major problem for soybean producers in the 1990s (Heap and Lebaron, 2001). Because of these problems, the introduction of transgenic glyphosate-resistant soybeans in 1996 resulted in a rapid shift toward glyphosate usage among soybean growers (Owen, 2000). Integration of glyphosate resistance is one of the best examples of a modern world agricultural technology altering the path of a world commodity crop. Unlike previous traits in soybean, the rapid commercial adoption of glyphosate-tolerant soybeans provided enhanced productivity and tangible benefits to the grower that fueled the trait adoption (James, 2001). Today herbicide tolerance is the most widely planted transgenic trait. In fact, over 85% of US soybeans and 56% of soybeans globally are now herbicide resistant (Castle *et al.*, 2006). The rapid rate of adoption in the United States would likely have been mirrored in other soybean-producing countries if the regulatory, intellectual property, and equity criteria for deployment of agricultural technology had been achieved (Conner *et al.*, 2004).

Glyphosate, under the brand name Roundup (registered trademark of Monsanto Company, St. Louis, MO), is the most widely used postemergent herbicide. This herbicide targets a broad spectrum of plant species and is nonselective. Glyphosate binds specifically to EPSPS, which is localized in the plastids (Steinrucken and Amrhein, 1980). Blocking this enzyme interrupts the shikimic pathway and prevents aromatic amino acid production necessary for protein synthesis and some secondary metabolites (Padgett *et al.*, 1996), thus killing the plant within days. Because the EPSPS gene is found in all plants, bacteria, and fungi but not in animals, glyphosate is harmless to animals. In addition, the chemical has favorable environmental qualities including strong adsorption to soil. Due to its nonselective nature, glyphosate cannot be used to prevent weeds in nontransgenic crops because it causes severe plant injury (Liu, 1999).

Glyphosate-tolerant crops have been pursued since the early 1980s (Duke, 1996). Two strategies have been employed to develop glyphosate tolerance in crop plants: identification of glyphosate-tolerant EPSPS and metabolic detoxification of the glyphosate molecule.

Glyphosate-tolerant EPSPS genes have been identified (Stalker *et al.*, 1985; Klee *et al.*, 1987; Barry *et al.*, 1992) for use in conferring transgenic glyphosate tolerance. The Roundup Ready trait was developed using this technology by Monsanto Company. The *aroA* gene from *Agrobacterium* sp. strain CP4 was isolated and found to have high tolerance to glyphosate when targeted to the chloroplasts in higher plants (Barry *et al.*, 1992). Two CP4 EPSPS constructs were created for transformation. Both consisted of pPV-GMGT04 (Padgett *et al.*, 1995), but one contained the CP4 EPSPS gene driven by the CaMV 35S promoter, and the other contained the CP4 gene controlled by the FMV 35S promoter (Table 3) (Gowda *et al.*, 1989). The gene was also fused to the petunia (*Petunia hybrida* Vilm.) EPSPS transit peptide in both constructs. The *GUS* gene was used as a selection marker (Jefferson *et al.*, 1986) and kanamycin resistance was included for bacterial selection on each plasmid. The plasmids were introduced into Asgrow cv. A5403 by particle bombardment as previously described by McCabe *et al.* (1988). Transformants with a positive germline were predicted by GUS expression patterns (Christou and McCabe, 1992). More than 300 lines were selfed and the T₁ seeds were screened for Roundup tolerance in the greenhouse (Padgett *et al.*, 1995). One line, 40-3, showed a high level of tolerance and was advanced by selfing. Four lines were generated and of these, line 40-3-2 demonstrated consistent glyphosate tolerance in the field (Padgett *et al.*, 1995). Line 40-3-2 was then used as the parental source of the CP4 EPSPS gene in the pedigrees of all subsequent Roundup Ready (RR) germplasm. Characterization of line 40-3-2 indicated that the transgenic locus is inherited as a single dominant gene and contains one functional insert of the CaMV 35S:CP4 cassette, an additional 254 bp fragment of the CP4 gene adjacent to its 3' untranslated region (Windels *et al.*, 2001), and a 72 bp segment of the CP4 gene that co-segregates with the functional CP4 cassette. The *GUS* gene and the FMV:EPSPS cassette were segregated out

in earlier generations and are not present in the final product.

To ensure that the CP4 protein is expressed correctly *in planta*, expression of the transgene was compared in plants and *E. coli*. Molecular weight, immunoreactivity, N-terminal sequence, glycosylation, and functional activity were compared from the two sources. In accordance with standard regulatory requirements, nutritional and compositional characteristics of the RR soybean were compared to those of the conventional soybean (Harrison *et al.*, 1996). Results showed that there were no significant differences in total protein, total oil, amino acid, and fatty acid concentrations.

GM RR soybean was subjected to rigorous safety assessment prior to regulatory approval and release. Food and Drug Administration (FDA) regulations mandate testing for allergenicity. The CP4 protein was subjected to *in vitro* digestibility studies in order to assess its ability to withstand degradation in the intestinal tract (Harrison *et al.*, 1996). One characteristic of potential allergens is their ability to resist degradation in the gastrointestinal tract (Astwood *et al.*, 1996). During analysis, the CP4 protein degraded within 15 s in simulated stomach fluid and within 10 min in simulated intestinal fluid. Furthermore, the CP4 protein is only present in the whole soybean seed at approximately 0.04% (Padgett *et al.*, 1995) and levels are significantly reduced during processing, whereas all known food allergens are present in the ingested product at a rate of 1–80% (Taylor, 1992). These data indicate that RR soybeans are as safe as conventional soybeans. With application of glyphosate to soybean fields, chemical residue on the plants is unavoidable. The EPA (2000) has identified acceptable glyphosate residue levels for seed: 20 mg kg⁻¹, hulls: 100 mg kg⁻¹, forage: 100 mg kg⁻¹, and hay: 200 mg kg⁻¹.

Initial studies reported that the RR transgene in soybeans had no negative impact on agronomic performance (Delannay *et al.*, 1995). However, several reports have been released claiming the contrary, including overdeposition of lignin leading to stem splitting (Gertz *et al.*, 1999) and yield loss (Benbrook, 1999; Carpenter, 2001; Elmore *et al.*, 2001b). True nearly isogenic lines with and without the RR trait are not available, making it impossible to distinguish if the yield loss effects are due to linkage drag or effects

caused by the transgene. Elmore *et al.* (2001a) conducted a field experiment studying the response of several RR soybean cultivars to glyphosate, ammonium sulfate, and water. They found that the glyphosate did not affect the grain yield. A study by Lappe *et al.* (1998) reported that the level of phytoestrogens is lower in RR soybeans, but the American Soybean Association (2002) countered that claim, stating that considering the environmental impacts on isoflavone levels, the phytoestrogen levels reported (Lappe *et al.*, 1998) were within the normal variation known to exist in soybean.

Glyphosate can be detoxified by various microbes (Barry *et al.*, 1992), which often occur in soils (Nomura and Hilton, 1977; Rueppel *et al.*, 1977). Transforming soybean with genes that detoxify glyphosate adds another mode of action against herbicide. Barry *et al.* (1992) isolated a glyphosate oxidoreductase gene from *Achromobacter* sp. Strain LBAA. They found that glyphosate tolerance could be induced in plants by expression of an optimized version of the gene. The glyphosate detoxification strategy has also been explored by Castle *et al.* (2004) and Siehl *et al.* (2005). Glyphosate acetyltransferase (GAT) enzyme was isolated in *Bacillus licheniformis* (Weigmann) Chester, a common saprophytic bacterium that has weak GAT activity. The enzyme detoxifies glyphosate by N-acetylation. Acetyl coenzyme A acts as an acetyl donor for the reaction and hydroxyl groups and primary amines are typically the acceptors. Kinetic properties of the enzyme were insufficient to confer glyphosate tolerance in transgenic plants. Through directed evolution, they were able to improve its activity 7000-fold and apply it toward transgenic glyphosate resistance in soybean. *B. licheniformis* genomic DNA fragments were expressed in *E. coli* and screened for N-acetylation activity. All active fragments contained a common region including an open reading frame of 438 bp coding for a 17 kDa protein. From this sequence, primers were constructed and used to identify three major alleles of GAT genes (93% identical) from several closely related strains (Castle *et al.*, 2006; Siehl *et al.*, 2005). DNA shuffling, a method for molecular recombination between genes (Stemmer, 1994; Ness *et al.*, 2002) has successfully been used to alter protein properties such as kinetics, substrate specificity, pH optimum, and thermal stability

and solubility (Cramer *et al.*, 1996; Zhang *et al.*, 1997). Castle *et al.* (2004) and Siehl *et al.* (2005) used this technology to improve the activity of the isolated *GAT* genes. The parental *GAT* genes were subjected to fragmentation-based, multigene shuffling. The development of synthetic shuffling in which synthetic oligonucleotides are used to add diversity to specific positions in a backbone template (Ness *et al.*, 2002) greatly improved the variants. Variants were tested by introduction into tobacco, *Arabidopsis*, and maize via *Agrobacterium*-mediated transformation. For the transgenic maize, maize ubiquitin promoter and potato PINII terminator (Table 3) were used to express the optimized *GAT* gene. Spray tests on T₀ maize plants transformed with *GAT* genes from the 5th to the 11th iteration of shuffling were also performed. A range of tolerance that correlated with the kinetic properties of the enzyme was observed. Most of the 11th iteration variants were asymptomatic at application rates of 4.5 lb AE A⁻¹ (5.45 kg AE ha⁻¹). Field trials are already underway to evaluate commercial potential of this type of glyphosate tolerance trait (Castle *et al.*, 2004; Siehl *et al.*, 2005). Currently Pioneer Hi-Bred is developing this trait in maize, soybean, and other crops, and they plan to offer *GAT* glyphosate resistance in combination with resistance to sulfonylurea herbicides (Castle *et al.*, 2006). This trait will provide an alternative form of glyphosate tolerance with several benefits including removal of herbicidal residue and possible spraying during reproductive development.

Glufosinate is a broad-spectrum grass and broadleaf contact herbicide. Usually sold under the name Liberty (Aventis Company) or Basta (Hoechst AG), it contains the active ingredient phosphinothricin (PPT), a compound similar in structure to the amino acid glutamine. Because of this similarity, PPT blocks the plant enzyme glutamine synthetase (GS) (Bayer *et al.*, 1972; Lea *et al.*, 1984), which is needed for nitrogen fixation and ammonia detoxification (Droge *et al.*, 1992). The plant death associated with glufosinate apparently results from the disruption of nitrogen assimilation metabolism (Wild and Wendler, 1990) and its indirect effect on photosynthesis (Wendler *et al.*, 1990, 1992; Wild and Wendler, 1990, 1993). The gene encoding L-phosphinothricin-N-acetyl transferase (*PAT*) was characterized and isolated from *Streptomyces viridochromogenes* Tu494

(Strauch *et al.*, 1988; Wohlleben *et al.*, 1988). The *BAR* gene encodes the same enzyme as *PAT* and was isolated from *Streptomyces hygroscopicus*. Both *PAT* and *BAR* convert PPT or bialaphos-based herbicides to the nonphytotoxic metabolite L-N-acetyl-PPT (Droge-Laser *et al.*, 1994) and prevent it from blocking the GS enzyme. Microbes readily metabolize PPT, making the half life in soil approximately 7 days. As a result, glufosinate has a very good environmental safety profile (Ahrens, 1994). Bayer CropScience developed commercial transgenic crop products using the trade name LibertyLink[®] (Castle *et al.*, 2006). Based on the assessment report from Food Standard Australia New Zealand (http://www.foodstandards.gov.au/_srcfiles/A481_GM_soy_FAR.pdf), Liberty-tolerant soybeans were developed by expression of the *PAT* gene under CaMV 35S promoter and CaMV 35S terminator (Table 3). The gene was synthesized with reduced GC content in order to optimize the plant expression and it encodes an amino acid sequence identical to the native *PAT* gene. The *PAT* transgenic lines, A2704 and A5547-127, were generated by particle bombardment and transgenic plants were selected by glufosinate. The two transgenic soybean lines demonstrated commercial levels of glufosinate resistance, passed all of the regulatory criteria, and were approved for commercialization in Canada in 1996 and United States in 1998. However, there is no commercial cultivation of the transgenic soybeans in these countries because of the wide acceptance of RR soybean. In addition, the European Union (EU) has not approved the LibertyLink soybean product yet.

2.2.6 Tolerance to abiotic stress

Generating transgenic crops with tolerance to abiotic stress is a big challenge for plant biotechnologists. The stresses include drought, cold, salinity, heat, and heavy metals. For soybean, drought is the most important stress inhibiting production. Progress is being made in soybean for engineering tolerance to abiotic stresses.

Luo *et al.* (2005) reported that a putative soybean plasma membrane cation/proton antiporter (CAX1) confers salt tolerance in *Arabidopsis*. The CAX (cation/proton exchanger)

family is potentially an important member for ion regulation in plant cells. *CAX1* was identified from a cDNA library containing sequences related to drought stress. The CaMV 35S promoter and Nos terminator were used to overexpress the *CAX1* gene in binary vector pBIN438 (Table 3). This construct was transformed into *Arabidopsis* by vacuum infiltration. Transgenic plants were identified by kanamycin selection on medium. T₃ *Cax1-Arabidopsis* plants accumulated less Na⁺, K⁺, and Li⁺, and were more tolerant to Na⁺ and Li⁺ stress compared to the control. Although the role that *CAX1* played in the drought stress response may be subtle, further studies should reveal its roles in overall plant stress response. This *CAX1* gene may be a good candidate for soybean salt tolerance during the germination stage.

Proline plays an important protective role on crops during drought stress since its accumulation can cause a decrease in osmotic potential (Good and Zaplachinski, 1994) and detoxify reactive oxygen species that are generated during drought stress (Guerrier *et al.*, 2000; Hong *et al.*, 2000). Simon-Sarkadi *et al.* (2005) reported that genetic manipulation of proline accumulation may confer tolerance to drought and heat in soybean. The gene encoding L-Δ¹-pyrroline-5-carboxylate reductase (*P5CR*), a key enzyme of the proline biosynthesis pathway, was isolated from *Arabidopsis*. The *P5CR* gene was overexpressed or antisense expressed under a heat shock-inducible promoter HS in an expression cassette (Table 3) (Ainley *et al.*, 1990). The construct was transformed into soybean by *Agrobacterium*-mediated transformation (De Ronde *et al.*, 2000). Transformed cells and plants were selected on kanamycin medium. Simon-Sarkadi *et al.* (2005) observed that antisense expression of the *P5CR* gene in T₃ plants reduced the level of proline and increased water loss, whereas overexpression of *P5CR* significantly increased the proline concentration in the plants and resulted in less water loss. The plants overexpressing the *P5CR* gene exhibited a higher photosynthesis capacity compared to the control and *P5CR*-silenced plants (De Ronde *et al.*, 2004). These results indicate that manipulation of proline level can confer tolerance to water stress in soybean plants (De Ronde *et al.*, 2000, 2001b, 2004; Simon-Sarkadi *et al.*, 2005). Engineering drought tolerance in model plants has made excellent progress (Umezawa *et al.*, 2006). The technology and

materials developed in other plants can be used to improve soybean's tolerance to drought stress.

Iron deficiency is a significant problem for soybean production in the upper Midwest region of the United States due to iron-limiting calcareous soils. In response to iron-limiting environments, soybean plants induce an active proton pump, a ferric iron reductase, and an iron transporter. Vasconcelos *et al.* (2006) reported that heterologous expression of the *A. thaliana* ferric chelate reductase gene, *FRO2*, in transgenic soybean significantly enhances Fe³⁺ reduction in roots and leaves. The *FRO2* gene was expressed under the CaMV 35S promoter in pPZP binary vector with the *BAR* gene as the selection marker (Table 3). This vector was transformed into soybean tissue by *A. tumefaciens* strain EHA101 (Zhang *et al.*, 1999; Xing *et al.*, 2000). Soybean transformation was conducted with genotypes Thorne (Ohio State University) and A3237 (Asgrow Seed Company). Transformants were selected on glufosinate-containing medium. An assay comparing the transgenic plants in Fe-treatments and control plants grown under hydroponics that mimic Fe-sufficient and Fe-deficient soil environments was performed. In the transgenic soybean plants, the ferric reductase activity significantly increased (threefold to 10-fold), leading to reduced chlorosis, increased chlorophyll concentration, and less biomass loss in the transgenic plants. However, the data indicate that constitutive expression of *FRO2* under noniron stress conditions may cause decrease in plant productivity. This research suggests that expression of an iron chelate reductase in soybean is a potential approach to control iron deficiency chlorosis.

With the advancement of functional genomics research in *Arabidopsis*, soybean, and other crops, a number of stress-regulation genes have been discovered and are being evaluated in plants (Vinocur and Altman, 2005; Umezawa *et al.*, 2006). Transgenic soybean plants with enhanced tolerance to abiotic stresses will be available in the future for soybean farmers.

2.3 Quality Output Traits

Soybean is a staple food worldwide mainly due to its high protein and oil contents. Soybean

seeds contain 20% oil, 40% protein, 22–23% carbohydrate, 3–6% fiber, and 3–6% minerals based on dry weight (Wang, 1997). The efforts of improving soybean seed quality have been focused on modifications of oil, protein, amino acid, flavor, and other compositions. We will discuss the transgenic improvement of these seed compositions toward increasing food and feed value of soybean products.

2.3.1 Oil modification

The soybean oil biosynthesis pathway is well understood (Ohlrogge and Browse, 1995; Yadav, 1996; Voelker and Kinney, 2001). Soybean oil, similar to other vegetable oils, contains five common fatty acids: palmitic acid (16:0, ~11%), stearic acid (18:0, ~4%), oleic acid (18:1, ~22%), linoleic acid (18:2, ~53%), and linolenic acid (18:3, ~8%) (Parrott and Clemente, 2004). Various desaturases have important roles in the conversion and balance of the five different fatty acids, which have distinct oxidative stabilities, physical properties, and health benefits. In addition to these five common fatty acids, there are also more than 200 chemically diverse uncommon fatty acids found in different rare plant species that are controlled by specific desaturases (Van de loo *et al.*, 1993; Yadav, 1996). Soybean scientists have been focusing on three objectives in the metabolic engineering of oil: producing more of the desirable fatty acids; producing less of the undesirable fatty acids; and producing natural but novel fatty acids in soybean seeds. The approaches taken to achieve these objectives include overexpression or co-suppression of soybean desaturase genes or desaturase genes from other plant species. As illustrated below, great progress has been made and unique soybean oils have been developed for various uses. There is great potential for improving soybean oil for food applications and industrial uses through soybean biotechnology (Mazur *et al.*, 1999; Drexler *et al.*, 2003; Kinney, 2006), we will focus on the food and feed application in this section.

Monounsaturated oleic acid (18:1) is preferred by consumers due to its health benefits and stability compared to the polyunsaturated linoleic (18:2) and linolenic (18:3) acids. Linolenic acid has low oxidative stability, which causes reduction in the performance, rancidity, and poor soybean oil

flavor over time. A key goal of improving soybean oil quality has been to increase its oxidative stability by reducing its linolenic acid (18:3) content. Hydrogenation can significantly improve oil stability and flavor; however, the process is expensive, and produces *trans*-fatty acids, which have human health risks. Oil containing low levels of saturates and polyunsaturates and high levels of monounsaturated fats would provide significant human health benefits and improved oil stability, as well as economic benefit to oil processors. Both mutation breeding and transgenic breeding have been used to identify soybean lines producing high oleic soybean oil (Takagi and Rahman, 1996; Mazur *et al.*, 1999). Transgenic soybean has been found to produce oleic acid in the oil as high as 85%, which is much higher than products developed through other methods.

A transgenic high oleic acid soybean line developed by DuPont Company was first commercialized in 1998 and the detailed information on the product was described by Kinney and Knowlton (1998) and Australia New Zealand Food Authority (ANZFA, 1991). Two constructs, pBS43 and pML102, were transformed into the shoot apex of the Asgrow cv. A2396 by particle bombardment. The plasmid pBS43 contained two transgene units: seed-specific promoter β -conglycinin:*FAD2-1*:phaseolin terminator (Table 3) and CaMV 35S promoter:*GUS*:Nos terminator. This construct was designed to introduce post-transcriptional gene silencing, also known as co-suppression or RNAi (Cerutti, 2003) of the *FAD2-1* gene (Matzke and Matzke, 1995; Singh *et al.*, 2000). The second construct, pML102, contained the *Corynebacterium* *dapA* gene encoding a lysine-insensitive version of dihydrodipicolinic acid synthase (DHDDS) flanked by the CaMV 35S promoter and the terminator of Kunitz trypsin inhibitor gene 3 (Table 3). This construct was designed to enhance the lysine level in the soybean seeds. High oleic progeny were developed from a single selfed transgenic line (260-05) derived from the co-transformation of pBS43 and pML102. The high oleic acid plants showed that the original transgenic line contained two loci, one locus possessed an element from pBS43 only, which is actually the silencing allele, and the other locus contains inserts from both plasmids. Further molecular studies revealed that this silencing allele contains two copies of pBS43 in an inverted repeat

orientation (Kinney and Knowlton, 1998; Parrott and Clemente, 2004).

Regulatory analysis of the high oleic soybean products included a comprehensive Northern blot and protein profiling. Protein profiling indicates that no new proteins are expressed in the transgenic soybean compared to the parental line; however, minor changes occurred in β -conglycinin due to co-suppression of the β -conglycinin promoter sequence (Kinney *et al.*, 2001a, b). To determine if the alterations in protein profile affect the allergenicity compared to the parental line, radioallergosorbent reactivity was measured using control sera and sera from 31 individuals who are known to have allergies to soybean extracts or other foods. No alteration in allergenicity was observed compared to the parental line. The analyses of amino acid content, total oil content, and oil compositions demonstrated that the high oleic acid soybean seeds are equivalent to the conventional soybean seeds except for the enhanced oleic acid level and alteration in protein profile. Data from feeding trials indicate that the meal from transgenic soybean is equivalent to that of the conventional soybean lines in term of its ability to support the growth and development of chickens and pigs.

Conversion of oleic acid to linoleic acid is controlled by a δ -12 desaturase encoded by the *FAD2-1* gene (Heppard *et al.*, 1996). Down-regulation of this gene causes an accumulation of oleic acid in transgenic seed oil up to 85% (Kinney, 1996; Mazur *et al.*, 1999; Buhr *et al.*, 2002). Palmitic acid is released from palmitoyl-acyl carrier protein (ACP) by palmitoyl-ACP thioesterase (*FAD3*). Buhr *et al.* (2002) silenced the embryo-specific *FAD2-1* and *FAD3* genes using ribozyme-terminated antisense constructs in soybean plants. Both genes were isolated from soybean by PCR (Heppard *et al.*, 1996). Seed-specific phaseolin promoter and CaMV 35S terminator were used to express *FAD2-1* in a binary vector (Table 3). Seed-specific β -conglycinin promoter and CaMV 35S terminator were used in the binary vector containing the fusion of *FAD2-1* and *FAD3* (Table 3). The CaMV 35S promoter-driven *BAR* gene cassette was used as a selection marker. These constructs were transformed into soybean (A3237) by *A. tumefaciens*-mediated transformation as previously described (Hood *et al.*, 1986; Hinchee *et al.*, 1988; Zhang *et al.*, 1999; Clemente *et al.*,

2000). Positive transformants were identified and selected by glufosinate during shoot initiation and elongation. Two of eight transgenic lines showed over 75% oleic acid content. Transformation with the dual constructs, simultaneously knocking off *FAD2-1* and *FAD3* genes, generated five events. These five events had oleic acid levels greater than 85% and saturated fatty acid levels less than 6%. The increase of oleic acid and decrease in saturated fatty acid was correlated to the reduction of the *FAD2-1* and *FAD3* mRNAs. These results clearly demonstrated that silencing desaturase and thioesterase genes can modify the oil compositions in soybean seeds.

Linolenic acid is an ω -3 fatty acid that is essential in mammalian diets. Romieu *et al.* (2005) reported that ω -3 fatty acids prevent heart rate variability reductions associated with particulate matter; therefore there is increasing interest in high linolenic oil from the nutritional standpoint. High linolenic oil has desirable properties for use as drying oils in coating applications such as paints, inks, and varnishes (see detail in the Section 2.4). Although high linolenic oil has low oxidative stability, the heart-healthy ω -3 fatty acid can be consumed in the form of soybean seeds, sprouts, or as tofu. High linolenic soybean lines have been generated through mutation breeding methods (Burton *et al.*, 2004). Seed-specific overexpression of the *FAD3* gene under β -conglycinin promoter and phaseolin terminator (Table 3), which encodes the enzyme that converts linoleic to linolenic acid, significantly increased linolenic acid content from 10% in the control to 50% in transgenic soybean lines (Cahoon, 2003). An increase in stearic acid (18:0) content in soybean oil is desirable for certain food-processing applications since it offers the potential for the production of solid fat products without hydrogenation (Spencer *et al.*, 2003). This would help to reduce the current health concern surrounding foods containing *trans*-fatty acids. Stearic acid concentration in soybean is determined by alterations in the δ -9 stearoyl-ACP desaturase (*SACPD*) gene, which encodes a soluble enzyme that converts stearic acid to oleic acid (Rahman *et al.*, 1997). Six soybean germplasm lines carrying the mutant *SACPD* alleles contain increased levels of stearic acid. Using *SACPD* genes to manipulate stearic acid content in oil has been demonstrated by Bidney *et al.* (2002). Antisense expression of a *SACPD* gene under

the Napin promoter and Nos terminator in sunflower significantly increased saturated fatty acids. The transgenic sunflower lines increased seed stearic acid content fourfold, producing over 40% saturated fatty acids. Similar antisense expression technology for increasing saturated fatty acid has also been used in other crops (Knutzon *et al.*, 1992; Singh *et al.*, 2000). Byfield *et al.* (2006) identified two *SACPD* genes in soybean that may provide the means to achieve stable production of high stearic acid soy oil. This oil has great potential for industrial use in products such as coating fat, soap, and margarine (Bidney *et al.*, 2002).

Medical studies have shown that diets high in saturated acyl compounds such as palmitic and stearic acids may increase blood serum cholesterol levels and the risk of coronary heart disease. New FDA labeling regulations require that a vegetable oil characterized as “low saturated” must contain less than 70 g kg⁻¹ total saturates. Conventional soybean oil contains 120–140 g kg⁻¹, therefore a reduction is required for the new market. The key enzyme in the biosynthesis of palmitic acid is 16:0-ACP thioesterase, which is encoded by the *FATB* gene. *FATB* gene mutants were identified by conventional breeding and a low palmitic acid soybean line was developed through mutation breeding (Burton *et al.*, 2004). As discussed previously, *FatB* gene silencing can significantly reduce palmitic acid levels in transgenic soybean (Buhr *et al.*, 2002). Blocking the exit of palmitoyl-ACP and stearyl-ACP from the plastid by silencing acyl-ACP thioesterase (*GmFatB1* and *GmFatB2*) genes resulted in a reduction in total saturated fatty acids from 14% to 3% (Kinney, 1996). Overexpression of a castor seed δ -9 stearyl-ACP desaturase in sunflower under a seed-specific promoter significantly reduced the stearic acid level in sunflower oil (Rousselin *et al.*, 2002). From these data, one can deduce that soybean *SACPD*-like genes or desaturase genes from other crops will be useful in manipulating stearic acid levels in soybean oil.

Many bioactive fatty acids have a significant impact on human health, but are not normally present in soybean oil. These unusual polyunsaturated fatty acids provide heart health benefits independent from soybean proteins (Martin and Valeille, 2002; Kelley and Erikson, 2003; Knapp *et al.*, 2003). It is possible to engineer soybean

with these useful polyunsaturated fatty acids to further improve the health benefits of soybean. For example, γ -linolenic acid and arachidonic acid are important for human health and nutrition (Napier and Michaelson, 2001). Genes encoding the desaturases that are responsible for the production of these fatty acids are available (Michaelson *et al.*, 1998; Hong *et al.*, 2002). Liu *et al.* (2001) expressed an 18:1 δ -12 desaturase either alone or in combination with 18:2 δ -12 desaturase in canola. The 18:1 δ -12 desaturase alone can increase linoleic acid by 46%, and the two enzymes together dramatically enhance the level of γ -linolenic acid up to 43% in the transgenic canola seeds. These genes could enable engineered soybean to produce high levels of γ -linolenic acid in soybean seed, improving its nutritional value.

Stearidonic acid (STA) has been considered as a valuable alternative source for ω -3 fatty acids since it can be more efficiently converted to eicosapentaenoic acid in animals compared to α -linolenic acid. Sato *et al.* (2004) expressed a borage δ -6 desaturase gene in soybean under seed-specific β -conglycinin promoter and CaMV 35S terminator (Table 3). The tobacco etch virus translation enhancer element was used to enhance the expression of the desaturase enzyme. The Nos promoter driving *BAR* gene cassette was used as a selection marker. The construct was transformed into somatic embryos by particle bombardment. Four δ -6 desaturase events were free of the *BAR* gene and one of the events, designated 420-5, was further evaluated in field studies (Sato *et al.*, 2004). Progeny from this event consistently produced γ -linolenic acid (up to 30%) and STA (up to 4%) under various environmental conditions. In an attempt to maximize the STA content of the soybean oil, Eckert *et al.* (2006) stacked a borage δ -6 desaturase and an *Arabidopsis* δ -15 desaturase through either sexual crossing of transgenic events, re-transformation, or co-transformation of both genes. Both genes were overexpressed under the control of the seed-specific soybean β -conglycinin promoter and CaMV 35S terminator (Table 3). The constructs were transformed into soybean by particle bombardment and the *BAR* gene was used as a selection marker. Overexpression of *Arabidopsis* δ -15 desaturase in soybean significantly enhanced the α -linolenic acid content. Notably co-expression of δ -15 and δ -6 desaturases together dramatically increased the

accumulation of STA, which can be as high as 29% of the total fatty acids in the transgenic soybean seeds. In terms of ω -3 activity, 29% STA is equal to about 60% of γ -linolenic acid. These transgenic soybean events are under further evaluation for product development.

Long-chain polyunsaturated fatty acids with 20 and 22 carbon atoms containing a few *cis*-double bonds (C20- and C22-LCPUFA) are very important for human development and health. However, humans cannot obtain C20- or C22-LCPUFA from vegetables. The major source of ω -3 LCPUFA in the human diet is from fish and fish products. Recently great progress has been reported in transgenic production of LCPUFA in oilseed crops (Domergue *et al.*, 2005). Kinney *et al.* (2004) co-expressed five genes under different seed-specific promoters and terminators in transgenic soybean embryos and seeds (Table 3). These five genes were isolated from *S. diclina* for Sd Δ 6-desaturase and Sd Δ 17-desaturase, *M. alpine* for Ma Δ 6-elongase and Ma Δ 5-desaturase, and *A. thaliana* for Sd Δ 15-desaturase. These genes were transformed into soybean by co-bombardment of two DNA inserts. One of the inserts contained three transgene units: (β -conglycinin promoter:Sd Δ 6-desaturase:phaseolin terminator), (glycinin Gy1 promoter:Ma Δ 6-elongase:pea leguminA2 terminator), and (trypsin inhibitor promoter:Ma Δ 5-desaturase:trypsin inhibitor terminator). The other insert contained two transgene units: (annexin promoter:Sd Δ 17-desaturase:BD30 terminator) and (trypsin promoter:Sd Δ 15-desaturase:trypsin terminator). Transgenic plants were selected by hygromycin B. These five genes established a biosynthesis pathway of eicosapentaenoic acid and resulted in the production of 19.6% eicosapentaenoic acid in the transgenic soybeans (Kinney *et al.*, 2004). The LCPUFA levels in the transgenic soybean seeds were as high as 35%, which is 59% higher than the level in salmon steak (Domergue *et al.*, 2005). Transgenic approaches in *Arabidopsis* and other oilseed plants have achieved very similar results (Abbadì *et al.*, 2004; Qi *et al.*, 2004). These are good examples of engineering a biosynthetic pathway in soybean seeds to produce nutritious oil products in oilseed crops.

New technology for gene expression and gene silencing in crop plants has been developed to manipulate the specific desaturase mRNA/enzyme

levels to desired concentrations. However, the expected effects on fatty acid compositions may not always be achieved. Kinney *et al.* (2001) summarized and discussed the challenges in genetic engineering for improving oil quality. The main factors that impact genetic manipulation efficacy include fatty acid flux, desaturase gene families, and intracellular transport of desaturase products in soybean. Other factors may also affect the ability to modify unsaturated fatty acid content in the oil of transgenic soybean plants. The expression or silencing of desaturase transgenes needs to be closely timed with oil biosynthesis for maximum effectiveness. Once the embryo begins to make oil, fatty acids become incorporated into the triglycerol. Any fatty acids made before the transgene becomes effective will be stored in their unaltered state. Therefore, the expression cassette should include the proper seed-specific promoter in combination with the right desaturase transgene. The recent reports on transgenic production of LCPUFA in oilseed crops clearly indicate that biotechnology skills have been advanced to meet some of these challenges (Kinney, 2006).

2.3.2 Protein modification

More than 70% of the protein consumed by humans is derived from legumes and cereals. Among the most commonly consumed food sources, soybean is the most protein-rich food (about 40% proteins) (Krishnan, 2005). Soybean isoflavones have been linked to reducing the risk of cancer and heart diseases, and soybean protein consumption can diminish chronic ailments such as osteoporosis, atherosclerosis, and renal diseases (Messina, 1999). Soybean is also extensively used as a high protein feed ingredient in livestock and poultry production. The health benefits of soybean consumption has increased consumer demand for new soybean products such as energy bars, breakfast cereals, meat alternatives, and beverages in the United States (Kinney, 2003).

The major soybean storage proteins are globulins including 2S, 7S, and 11S. The names were designated based on the sedimentation coefficients of the proteins in sucrose gradient centrifugation (Thanh and Shibasaki, 1976). The 7S and 11S globulins are also known as conglycinin

and glycinin and account for about 30% and 40% of the total seed protein, respectively (Nielsen, 1996). Genes encoding conglycinins and glycinins have been isolated (Krishnan, 2005). Conglycinin exists as a trimer consisting of α (76 kDa), α (72 kDa), and β (53 kDa) subunits (Thanh and Shibasaki, 1976, 1978; Coates *et al.*, 1985; Tierney *et al.*, 1987). Glycinin is present in hexamers and consists of acidic and basic subunits from a same precursor (Barton *et al.*, 1981; Beachy *et al.*, 1981). Glycinin contains significantly more sulfur amino acids, such as cysteine and methionine, than β -conglycinin (Krishnan, 2005). Approaches to enhancing soybean protein quality include conventional breeding in combination with mutation breeding with the purpose of increasing seed storage protein levels such as glycinin and β -conglycinin in soybean seeds (Krishnan, 2005), expression of sulfur-rich proteins with well-balanced amino acid compositions (see detail in the amino acid modification), and increasing the levels of abundant and low abundant proteins by transgenic engineering.

Both glycinin and conglycinin proteins are encoded by large gene families (Harada *et al.*, 1989; Beilinson *et al.*, 2002). Kinney and Fader (2002) isolated the soybean genes encoding glycinin and conglycinin. To determine whether β -conglycinin in developing soybean cotyledons could be targeted by co-suppression, truncated cDNA fragments of the α - and α -subunits of β -conglycinin were prepared using RT-PCR. The fragments were then cloned into an antisense expression cassette under β -conglycinin promoter and phaseolin terminator (Table 3). Similarly the five glycinin genes were cloned from genomic or cDNA clones and then subcloned into an antisense expression vector under the β -conglycinin promoter and phaseolin terminator. These constructs were transformed into soybean somatic embryos by particle bombardment. Hygromycin B was used as a selection agent. The conglycinin and glycinin proteins were visualized by SDS-PAGE, and transgenic soybean lines that produce no 7S or no 11S protein were identified. In these lines, the reduction of one protein class is compensated by an increase in the other class since the total protein level was maintained in the transgenic seeds. These transgenic lines provide excellent material for studying protein functionality and providing potential new soybean protein products with

unique functional properties. Soybean storage proteins such as 7S can reduce blood low-density lipoprotein (LDL) cholesterol concentration in humans (Sirtori and Lovati, 2001; Weggemans and Trautwein, 2003). In addition, soybean proteins together with isoflavones may reduce bone loss in postmenopausal women (Potter *et al.*, 1998). The transgenic lines with no 7S or 11S protein (Kinney and Fader, 2002) will be useful in studying the mechanism of reducing LDL cholesterol reduction.

Protein engineering technology enables artificially designed proteins with desirable functional properties to be introduced into soybean. It is possible to express novel proteins in soybean seeds and develop novel and desirable soybean protein products. Glycinins are encoded by at least five genes (Nielsen *et al.*, 1989), including a hypervariable protein domain. Scientists have been trying to insert sulfur amino acid residues into this domain (Nielsen *et al.*, 1990). It is possible to engineer extra methionine residues into the variable glycinin domain and the modifications have little impact on its stability (Gidamis *et al.*, 1995; Takaiwa *et al.*, 1995). These modified versions of glycinin genes are good candidates for improving the protein value of soybean seeds.

Some low abundant soybean proteins also have potential to be used for improving the protein value. Examples include directly expressing methionine-rich proteins (Galvez *et al.*, 1997) and overexpressing PIs to induce altered levels of amino acids (Kennedy, 1998). Overexpression of genes encoding Bowman-Birk chymotrypsin and trypsin inhibitors significantly increased the sulfur amino acid level in soybean seeds, and the inhibitor protein may be beneficial to humans since it may have anticarcinogenic properties (Kennedy, 1998). However, PIs have been shown to have a negative impact on the performance of nonruminants such as poultry and swine. Therefore, increasing sulfur amino acids by expressing PIs is not desirable.

Soybean seeds store a large amount of protein during their maturation phase in specific bodies known as protein storage vacuoles (PSV). In order to alter the nutritional quality of seed proteins and to enable production of recombinant proteins in the soybean seeds, it is necessary to localize transgenic proteins to the PSV (Kusnadi *et al.*, 1997; Horvath *et al.*, 2000). Maughan *et al.* (1999) cloned a gene encoding the bovine

milk protein, β -casein, into a seed-specific lectin promoter expression cassette (Table 3), and it was introduced into soybean somatic embryos via particle bombardment. A chimeric lectin β -casein gene was fused to the N-terminal signal peptide (32 amino acids) of soybean seed-specific lectin, and the lectin 3' UTR was used as a terminator. Transgenic plants were selected by hygromycin. Subsequent analyses on the transgenic plants were completed by Philip *et al.* (2001). Southern blot assay indicated that there are 4–8 copies of the β -casein gene in a single locus and Northern blot assay detected an enhanced level of casein mRNA in the developing cotyledons. Bovine β -casein protein was detected by Western blot assay in the cotyledons. The β -casein protein was purified from the immature soybean seeds by immunoaffinity chromatography and analyzed by two-dimensional gel electrophoresis, blotting, and N-terminal sequencing. The results demonstrated that the 32 amino acid signal peptide at the N-terminus of the chimeric β -casein was cleaved precisely from the protein. The recombinant soybean β -casein protein was not phosphorylated, causing a size difference compared to the soybean and native bovine β -casein protein on SDS–PAGE. Immunolocalization experiments demonstrated that the recombinant casein protein was localized in the PSV and accumulated to a high level in developing and mature soybean seeds. The addition of the β -casein milk protein into soybean seeds has the potential to increase soybean value. This is the first experiment showing the expression of a milk protein in soybean, showing that it is possible to improve protein quality in soybean by introducing foreign proteins controlled by seed-specific promoters. These results also suggest that this system could possibly be used for growing pharmaceutical or other valuable recombinant proteins in soybean seed, such as monoclonal antibodies (Zeitlin *et al.*, 1998).

Food allergies can cause nutritional problems in children and adults. Any food that contains protein has the potential to elicit an allergic reaction. Increased awareness of the many health benefits of soy protein, along with improved isolation techniques resulting in better flavor and increased functionality, has resulted in widespread use of soybean proteins in food products such as soymilk. This food development provides benefits to human health; however, the increasing use of

soybean products in processed foods brings a potential threat to soybean-sensitive individuals (Vidal *et al.*, 1997; Herman, 2005). The abundant storage proteins and a few less-abundant seed proteins are potential allergens. One of these low abundance proteins, P34 (also known as Gly m Bd 30K), is a major soybean allergen (Herman, 2005). Herman *et al.* (2003) isolated the *P34* gene from soybean by PCR amplification. Seed-specific β -conglycinin promoter and phaseolin terminator were used to express the *P34* gene (Table 3), and the hygromycin B phosphotransferase gene under control of CaMV 35S promoter was used for selection of transformants. This construct was transformed into soybean embryos by particle bombardment and transgenic tissue was selected on medium containing hygromycin B. Western blot assays using the P34 monoclonal antibody were used to identify homozygous *P34*-transgenic soybean plants, which showed dominant Mendelian inheritance and stability of the trait for three generations. The *P34*-transgenic soybean plants exhibited normal agronomic performance such as seed size, shape, protein content, and oil content as compared to the controls. Analysis of seeds from T₃ homozygous lines revealed that the protein profile is the same as the parental lines except for significantly reduced levels of the P34 protein. These data provide evidence that one of the dominant allergens of soybean seeds can be reduced while maintaining substantial equivalence of composition in transgenic seed. Joseph *et al.* (2006) identified 12 P34 null lines that contain P34 protein at a low level, likely due to a site mutation in the *P34* open reading frame that destabilizes the P34 protein. These mutant genes are candidates for reducing P34 protein in transgenic soybean seeds. In addition, backcrossing the silencing allele in the transgenic line generated by Herman *et al.* (2003) into the P34 null lines may further reduce the level of P34 protein in soybean seeds. Soybean products with low levels of P34 protein can benefit people with soybean allergies.

2.3.3 Flavors

Many people wish to consume more soybean products due to the recent reports on their health benefits. However, the flavor of conventional soybeans has been described by many as painty,

grassy, beany, metallic, and bitter. Although some people like the natural soy flavors, these negative flavors are the limiting factor for the widespread development of soybean food products. Improving soybean flavors can be achieved by conventional breeding and transgenic methods through reducing the bad flavors and/or increasing the good flavors. For example, the beany flavor can be reduced or removed by reducing lipoxygenase activity in transgenic soybean plants (Kitamura, 1995). Physically changing functional properties including solubility, water absorption, viscosity, and flavor binding can also impact soybean flavor (Adler-Nissen, 1978; Kinsella, 1979; Kitamura, 1995).

The driving force behind soybean food products is the health properties of soybean food compositions. Soybean isoflavones have benefits to human health (Fader *et al.*, 2000; Liu *et al.*, 2002). They also have natural roles in plant defense and root nodulation (Subramanian *et al.*, 2004). Soybean isoflavone synthase genes were isolated through a yeast expression assay for screening soybean ESTs encoding cytochrome P450 proteins. Isoflavone synthase genes were also isolated from several other legume plants using the soybean isoflavone synthase gene as a probe (Jung *et al.*, 2000). When expressing soybean isoflavone synthase in the nonlegume plants *A. thaliana* and rice, genistein was able to accumulate (Jung *et al.*, 2000; Sreevidya *et al.*, 2006). This result indicates that beneficial isoflavones can be produced in nonlegume crops that may not have the taste of soybean. In addition, isoflavone synthase may elevate the capacity of defense and nodulation in crops (Subramanian *et al.*, 2004; Sreevidya *et al.*, 2006). Isoflavone synthase genes are useful in the transgenic efforts of enhancing the nutritional value in crops.

Many of the unfavorable flavors associated with the soybean are due to oxidation of polyunsaturated fatty linoleic and linolenic acids (Frankel, 1987). High oleic soybeans have reduced polyunsaturated fatty acid levels (Kinney, 1996; Kinney and Knowlton, 1998). By silencing the *FAD2-1* gene (see detail in the Oil Modification section), Kinney and Knowlton (1998) decreased the linolenic acid content from 70% to 5%, leading to increased oxidative stability of the high oleic soybean oil. In addition, the transgenic soybean seeds produce significantly reduced levels (five fold to 10-fold) of lipid oxidation products, such as

2-pentyl furan and trans 2-hexanal in flours and protein isolates. This leads to reduced grassy and beany flavors in the various products from the high oleic soybean, however, some grassy flavor is still present. Combining the high oleic lines with other transgenic lines that have reduced or removed lipoxygenase (Hildebrand, 1989) and/or hydroperoxide lyases (Noordermeer *et al.*, 2001) can further reduce the grassy flavor (Kinney, 2003).

The nonvolatile compounds that contribute to bitter and astringent flavors of soybean proteins are less understood. These flavors may be involved in the biosynthesis of small peptides, flavonoids, phenols, and saponins (Drewnowski, 2001). Reduced levels of these flavors may be achieved by transgenically reducing the synthesis of these compounds (Kinney, 2003); however, some of these compounds may have health benefits in soybean products (Messina *et al.*, 2002). Transgenic products with less bitter flavor may be achieved with better understanding of biosynthesis pathways of the secondary compounds.

2.3.4 Amino acid

Mammals obtain essential amino acids such as lysine from foods. Lysine is an essential amino acid that is limiting in soybean food and feed. Two of the key enzymes in the lysine biosynthesis pathway, aspartokinase (AK) and DHDPS, have been isolated from bacteria or other sources for increasing lysine levels in seeds. These two enzymes are feedback inhibited by lysine (Mazur *et al.*, 1999). Falco *et al.* (1995) isolated a gene encoding a lysine-insensitive AK mutant, *lysC*, from an *E. coli* genomic library, and a DHDPS *dapA* gene from *Corynebacterium* by PCR amplification. The AK enzyme encoded by a gene from *E. coli* gene has a substitution of isoleucine for threonine at amino acid position 352. This site mutation is responsible for the enzyme's insensitivity to lysine. Plant deregulated enzymes were also studied, but they showed inconsistent results (Falco *et al.*, 1995). The DHDPS and AK enzymes were linked to a chloroplast transit peptide and expressed in transgenic canola and soybean seeds. The seed-specific phaseolin promoter and its terminator were used in the construct expressing the *AK* and *DHDPS* genes (Table 3). These constructs were transformed into soybean by particle bombardment. GUS

visualization and PCR analysis were used to select the positively transformed soybean plants. Expression of DHDPS resulted in more than a 100-fold increase in the accumulation of free lysine in the seeds of canola; total seed lysine content approximately doubled. Expression of both DHDPS and the lysine-insensitive AK in soybean transformants similarly caused a several 100-fold increase in free lysine, and increased total seed lysine content by as much as fivefold. These data indicate that microbial genetic materials are useful in plant engineering.

Zhu and Galili (2003, 2004) expressed the bacterial feedback-insensitive DHDPS in a seed-specific manner in wild-type *Arabidopsis* as well as in an *Arabidopsis* knockout mutant with increased levels of lysine. Transgenic plants expressing the *DHDPS* gene contained 12-fold and fivefold higher levels of seed free lysine, respectively. Their results show that lysine catabolism plays a major regulatory role in balancing lysine levels in *Arabidopsis* seeds. To increase the lysine level in soybean seeds, we should consider increasing the synthesis and decreasing the catabolic rate. In addition, lysine content can be enhanced by the expression of lysine-rich protein for increasing methionine content as illustrated below.

The low sulfur content of conventional soybean seed protein is not optimal for ration formulations in the human diet and animal feed. Therefore, increasing the methionine and cysteine content of soybean seed proteins can increase the nutritional value of the soybean seeds. Methionine-rich 2S albumin from Brazil nut was introduced into transgenic soybean plants. Overexpression of Brazil nut 2S albumin (containing 18% methionine and 8% cysteine) significantly increased the methionine content, potentially increasing nutritional value (Townsend and Thomas, 1994). In the transgenic soybean lines, the albumin protein can accumulate to as much as 10% of the total seed protein and increase the overall methionine content by 15–40% (Townsend and Thomas, 1994). However, the Brazil nut 2S albumin protein is a major allergen (Nordlee *et al.*, 1996) and this transgenic approach was not developed further. Sunflower albumin is also a sulfur-rich protein and has potential in engineering high sulfur soybean products (Wang *et al.*, 2001); however, it also has potential to be an allergen (Kelly *et al.*, 2000).

Dinkins *et al.* (2001) demonstrated that overexpression of maize 15 kDa zein protein could

confer higher levels of methionine and cysteine in soybean seed. The zein gene encoding the 15 kDa zein protein along with a portion of the zein 3'UTR was isolated from maize. The seed-specific β -conglycinin promoter and Nos terminator were used to express the 15 kDa zein protein (Table 3). The construct was transformed into soybean somatic embryo cultures by particle bombardment and hygromycin was used to select the transgenic tissues. Transgenic soybean plants from two transgenic lines were characterized by Southern blot analysis, and multiple copies of zein genes were revealed in the transgenic plants. Amino acid analysis indicated that methionine and cysteine levels in the transgenic lines increased 12–20% compared to the control. Kim and Krishnan (2004) reported the expression of an 11 kDa methionine-rich δ zein in soybean. They isolated the *zein* gene from maize inbred line W23a1, and cloned the gene between β -conglycinin promoter and potato protein inhibitor II (*PINII*) terminator for seed-specific expression in transgenic soybean seeds (Table 3). This construct was transformed into soybean cotyledons by *Agrobacterium*-cotyledon node transformation (Hinchee *et al.*, 1988) utilizing glufosinate as a selection agent (Zhang *et al.*, 1999). Overexpression of the zein protein gene significantly enhanced the methionine content in the alcohol-soluble protein fraction even though overall methionine content of the seed protein remained the same. Recently, Li *et al.* (2005) expressed the maize 27 kDa γ -zein gene (Prat *et al.*, 1985) in transgenic soybean plants under β -conglycinin promoter and β -conglycinin terminator (Doyle *et al.*, 1986) (Table 3). The transgene construct was transformed into somatic embryogenic cultures by particle bombardment and transgenic plants were selected on medium containing hygromycin B. Transgenic T₁ and T₂ seeds consistently showed enhanced expression of the γ -zein protein. Up to 6.49% of the alcohol-extractable proteins from the transgenic seeds were the γ -zein protein. In the transgenic seeds, the content of cysteine and methionine increased about 30% compared to the nontransformed control (Li *et al.*, 2005). These results indicate that sulfur amino acid composition in soybean seeds can be modified by overexpressing a plant sulfur amino acid-rich protein gene.

Krishnan (2005) reviewed the research efforts on enhancing sulfur amino acid content in transgenic soybean seeds. Traditional breeding has been

primarily utilized to increase the total protein content but not to enhance the sulfur amino acid content of soybean. Compared to the conventional breeding method, genetic engineering appears to be a more realistic approach. As discussed above, introduction of methionine-rich heterologous proteins has resulted in a modest increase of this amino acid in soybean. A better understanding of the sulfur assimilatory pathway in soybean will provide additional information to enhance the research on increasing sulfur amino acid level in soybean seeds. Expression of feedback-insensitive forms of serine acetyl transferase and *O*-acetylserine (thiol) lyase, two key enzymes in the sulfur assimilatory pathway, could lead to an increase in the availability of sulfur amino acids (Krishnan, 2005). An alternative approach is to express a synthetic protein such as MB1 or APS1 that has well-balanced sulfur amino acids (Chassy *et al.*, 2004). *ASP1* is such a synthetic gene that encodes 80% of essential amino acids and has four 20-amino acid helical-repeating monomers. These synthetic genes have been successfully expressed in crops (Kim *et al.*, 1992; Beauregard *et al.*, 1995; Zhang *et al.*, 2002; Potrykus, 2003) and are excellent candidates for engineering soybean.

In addition to the sulfur amino acids, isoleucine, tryptophan, valine, and arginine have been identified as “second tier” limiting amino acids in animal feed (Krishnan, 2005). Studies on increasing these amino acids have been pursued. Rapp *et al.* (2003) transformed soybean plants to produce 10–20 residues of isoleucine, tryptophan, methionine, or arginine. The synthetic genes were expressed under β -conglycinin promoter and terminator, and the construct was introduced into soybean via *Agrobacterium*-mediated transformation. Expression of the extra amino acids had no impact on the β -conglycinin structure and protein folding but conferred increased levels of the “second tier” amino acids (Rapp *et al.*, 2005).

2.3.5 Vitamin E

The nutritional value of vitamin E in the human diet was recognized long ago (Evans and Bishop, 1922). Vitamin E is a group of compounds (vitamers) including eight major forms of α -, β -, γ -, and

δ -tocopherol and four corresponding unsaturated derivatives, α -, β -, γ -, and δ -tocotrienol (Van Eenennaam *et al.*, 2003). Medical evidence shows that daily vitamin E supplementation of 400 IU (250 mg of RRR- α -tocopherol) can significantly reduce the risk for cardiovascular disease and cancer, in addition to preventing or slowing degenerative diseases (Buring and Hennekens, 1997; Tangney, 1997; Bramley *et al.*, 2000). Soybean seeds synthesize tocopherols and have significant amounts of γ -tocopherol (60–65% of the total) and δ -tocopherol (20–26% of the total) (Tan, 1989), however, these tocopherols have low activity. Conversion of the less active tocopherols to the active α -tocopherol form by manipulating the seed tocopherol biosynthetic pathway can increase soybean food value and benefit human health.

Cahoon *et al.* (2003) isolated a barley cDNA encoding homogentisic acid geranylgeranyl transferase (HGGT), which catalyzes the key step of tocotrienol biosynthesis. The barley *HGGT* gene was cloned between the CaMV 35S promoter and *Nos* terminator (Table 3). This construct was transformed into *Arabidopsis* by *Agrobacterium*-mediated transformation. Transgenic *Arabidopsis* plants were identified by kanamycin selection. Overexpression of the barley *HGGT* in *Arabidopsis* resulted in a 10–15-fold increase in total vitamin E antioxidants. Similar results were obtained in transgenic maize seeds. This result shows that vitamin E content can be improved by manipulation of a single transgene that redirects metabolic flux.

Van Eenennaam *et al.* (2003) isolated the *Arabidopsis* gene (*At-VTE3*) encoding the tocopherol biosynthetic enzyme 2-methyl-6-phytylbenzoquinol methyltransferase by map-based cloning. *At-VTE4* cDNA was obtained by PCR amplification. Three expression constructs were made: two of them express either *At-VTE3* or *At-VTE4* under the control of the β -conglycinin promoter (Chen *et al.*, 1986; Wang and Dubois, 2003) with a 3' untranslated region from pea SSU (Table 3). The third construct contains the two expressing units. The *At-VTE3* and *At-VTE4* expression cassettes were cloned individually and jointly into a plant binary expression vector containing a CaMV 35S promoter driving CP4 cassette as a selectable marker (Martinell *et al.*, 2002). *A. tumefaciens*-mediated transformation

was carried out as described previously (Martinell *et al.*, 2002) using freshly germinated soybean meristems that were induced to form shoots. Seed-specific expression of *At-VTE3* in transgenic soybean reduced seed δ -tocopherol from 20% to 2%. When *At-VTE3* was co-expressed with *At-VTE4* in soybean, the seed accumulated more than 95% α -tocopherol, a dramatic change from the normal 10%. The Vitamin E activity increased fivefold in the transgenic soybean seeds. These results show the utility of genes from other plants in altering soybean tocopherol composition toward improving soybean nutritional quality. DellaPenna (2005) and Kinney (2006) reviewed the progress of manipulation of vitamin E synthesis in plants. Technology developed in other plants can be applied in soybean.

2.3.6 Phytate

Soybean meal contains a high level of phosphorus in the form of phytate. Unfortunately, phytate is largely unavailable to poultry and swine (Denbow *et al.*, 1998). Nelson *et al.* (1997) reported that mixing phytase enzymes with soybean feed formulations can increase the availability of phosphorus. Denbow *et al.* (1998) also pursued a transgenic approach to increase the availability of phosphorus. They isolated a *phytase* gene from *Aspergillus niger* by PCR based on the published sequence and expressed the gene under CaMV 35S promoter and Nos terminator (Table 3) (Depicker *et al.*, 1982). The tobacco leader sequence was used to enhance the expression level of the *phytase* gene (De Loose *et al.*, 1991). This construct was transformed into soybean plants (Asgrow A5403) by particle bombardment and transgenic plants were identified by kanamycin (nptII) selection as described by McCabe *et al.* (1988). The seeds from these events were evaluated using a chicken feeding assay. The results indicated that *phytase*-transgenic soybean seeds were comparable to fungal phytase-treated diets in term of increased growth rate, feed intake, toe ash weight, energy, and phosphorus digestibility. This study indicated that phytase can improve broiler performance when provided either as a commercial supplement or in the form of transformed soybeans.

Chiera *et al.* (2004) was able to recover fertile transgenic soybean plants transformed with

the soybean *phytase* gene. The *phytase* gene was cloned from soybean and overexpressed under the seed-specific β -conglycinin promoter and terminator (Table 3). The construct was transformed into soybean suspension cell cultures by co-bombardment with a hygromycin resistance gene construct. Transgenic cells were selected by hygromycin (Finer and McMullen, 1991). Phosphorus availability increased almost threefold and a 25% reduction of phytate level was observed in the transgenic soybean seeds (Chiera *et al.*, 2004).

Nunes *et al.* (2006) reported that RNAi-mediated silencing of myo-inositol-1-phosphate synthase gene (*GmMIPS1*) in soybean can reduce the phytate content. In soybean, myo-inositol-1-phosphate is synthesized from glucose 6-phosphate in a reaction catalyzed by the enzyme GmMIPS. INositol can be converted into phytic acid through a sequential phosphorylation of iNositol phosphates, and/or in part through phosphatidyliNositol phosphate. To understand the role of the *GmMIPS1* gene, transgenic soybean lines were produced using a hairpin construct (Wesley *et al.*, 2001) with the CaMV 35S promoter and octopine synthase (OCS) terminator (Table 3). Transgenic progenies were identified by PCR assay and confirmed by Southern blot assay. Expression levels of the *GmMIPS1* gene were detected by RT-PCR analysis. Phytic acid was determined by high performance liquid chromatography (HPLC) using a modification of the procedure described by Sandberg and Ahderinne (1986). The phytate level in the transgenic soybean seeds reached levels as high as 94% without any negative effect on the plant phenotype. Completely silencing this gene, however, may be lethal to seed development since iNositol plays a role in membrane trafficking and signaling in addition to regulating cellular metabolism and controlling growth.

2.4 Industrial Uses

Soybean seeds have a long history of industrial use (Tao, 1994). They contain approximately 40% protein and 20% lipids, both of which are used in industry. More than 600 million pounds of soybean oil are used for nonedible applications annually, including industrial material production

in the United States (Cahoon, 2003). Recently soybean's industrial usage has been highlighted by biofuel since it is a renewable energy source. The physical and chemical properties of conventional soybean oil limit its use in many industrial applications. Genetic engineering provides a great opportunity to improve the properties of soybean oil for industrial usage (Duffield *et al.*, 1998; Cahoon, 2003).

2.4.1 Biodiesel and other oil-based usages

Biodiesel (or biofuel) consists of mono alkyl ester-based fuels produced through *trans*-esterification of vegetable oils or animal fats. Glycerine is a by-product of the process which has more than 1600 commercial applications ranging from toothpaste to environmental-friendly antifreeze. The concept of using vegetable oil in engines started in 1895 when Rudolf Diesel developed the first engine to run on peanut oil (<http://www.cyberlipid.org/glycer/biodiesel.htm>). Pure biodiesel can be used in modified engines or it can be blended with petroleum diesel for use in standard engines. It has the same energy efficiency as petroleum diesel but provides many environmental benefits including low toxicity, high biodegradability, and high cetane number. Biodiesel has also been found to extend the life of engines. The main challenge preventing biodiesel from becoming mainstream is the relatively high cost of raw vegetable oil feedstock and the costs involved with the *trans*-esterification process. Many countries have initiated biodiesel-related projects and have supported the development and application of the technology since the late 1990s.

Conventional soybean oil contains a large quantity of linolenic acid and therefore has relatively low oxidative stability that impacts biodiesel quality (Knothe, 2004; Ferrari *et al.*, 2005). Scientists at DuPont have developed transgenic soybeans that produce oil with high oleic (80%) and low saturated fatty acid (6%), as well as low polyunsaturated fatty acid (5%) by knocking off the *FAD2* gene (Kinney, 1997; Kinney and Knowlton, 1998; Parrott and Clemente, 2004). This type of soybean oil has high oxidative stability

and is useful for biodiesel. This is an example of modifying soybean oil profile for improving the biodiesel blends (Kinney and Clemente, 2005). Another approach involves producing high concentrations of industrially useful fatty acids in plant seeds using the transgenic approach (Cahoon, 2003; Jaworski and Cahoon, 2003) (see detail in Section 2.4.3). This is an excellent example of how biotechnology links agriculture and industry.

Polyols are chemical compounds that contain multiple hydroxyl groups. Petroleum-based polyols are commonly used in manufacturing polyurethane plastic products. Soybean oil can also be used to produce polyols (Crandall, 2002). At least two types of soybean polyols have been prepared from soybean oil by chemical epoxidization. The properties of epoxidized soybean oil can be improved by using more homogenous fatty acids such as oleic acid. Natural plant lipids provide excellent lubrication and surface coating; however, their viscosity and oxidative reactivity limit their usage in modern high temperature applications. This is mainly due to the presence of multiple double bonds and ester linkages in the soybean oil. Transgenic high oleic soybean produces oil that contains more than 80% oleic acid with high oxidative stability, which is ideal for lubricant uses and polyol production (Kinney and Knowlton, 1998; Cahoon, 2003). Currently, the DuPont high oleic soybeans are commercially used for biodegradable lubricant formulations (Cahoon, 2003).

Rubber can be produced from soybean oil through chemical polymerization (Andjelkovic and Larock, 2006). Preliminary results indicate that these biobased products may be useful alternatives to current petroleum-based polymers for use in rubber products including tires. Plasticizers derived from epoxidized soybean oil are commercially available. They are primarily used to keep plastics and rubber soft and pliable in flooring, upholstery, food packaging, hoses, tubing, blood bags, and other products. The epoxy functionality of soybean oil provides excellent heat and light stability. Transgenic modification of fatty acid composition in soybeans, such as increasing the conjugated fatty acid content, can further improve the properties of the novel polymers toward producing nonpetroleum based rubber.

2.4.2 Plastic and other protein-based usage

Disposable plastic products are a part of every day life in many parts of the world, from drinking cups to food containers. Scientists have found that soybean proteins are a more environment-friendly and biodegradable material for making these products (American Soybean Association and United Soybean Board, 2004). The indestructibility of petroleum-based plastic is a growing concern because of its accumulation in the environment. The development of plant-based plastics, which are biodegradable by humidity and microorganisms, has made significant progress after the pioneering research by Jay-Lin Jan at Iowa State University in the United States (Paetau *et al.*, 1994). There is increasing interest in using natural plant fibers as reinforcements for plastics. Natural oils are useful raw materials in polymer synthesis. In the United States, the major source of vegetable oil for industrial applications is soybean oil. The biodegradable polymers will soon be commercialized in competition with commodity plastics offering lower cost, enhanced performance, and reduced weight compared to the petrochemical-based plastic products. Liu *et al.* (2006) reported “green” composites obtained from a mixture of epoxidized soybean oil and epoxy resin, 1,1,1-tris(p-hydroxyphenyl)ethane triglycidyl ether (THPE-GE), reinforced with flax fiber. The resulting composites have sufficient mechanical properties for agricultural equipment, civil engineering, and the automotive and construction industries. There are examples of producing polyhydroxyalkanoate (PHA) polymers in transgenic plants (Snell and Peoples, 2002). PHAs are polymers of hydroxyacids synthesized by a range of bacteria and can be used as biodegradable plastics. Three to four genes control the PHA or related polymer synthesis and these genes have been isolated from bacteria (Slater *et al.*, 1999; Bohmert *et al.*, 2000). Expression of these enzymes in plants can produce the PHA polymers (Snell and Peoples, 2002). These genes may be used to engineer soybean toward producing novel plastics.

High performance flax fiber made from plants is a potential substitute for glass or carbon fibers (O'Donnell *et al.*, 2004). Soybean protein textile fiber technology is also being pursued to provide alternatives to synthetic fibers. Soybean protein can be made into an inexpensive, washable, silklike

fabric. Research on chemical modification of soybean protein for industrial uses is underway (Tao, 1994; United Soybean Board Bulletin on Soybean Utilization, 1997). Spider dragline silk is a fiber with unique toughness and strength. It has potential to be used in medical materials and industrial fabric (Kaplan *et al.*, 1997). However, it is impossible to produce mass amounts of dragline silk from spiders. Barr *et al.* (2004) reported a method of producing and purifying recombinant silklike protein in soybean somatic embryos. A plant codon-optimized dragline silklike protein gene (*DP1B*) was synthesized based on the spider dragline silk protein sequence. The β -conglycinin promoter and the phaseolin terminator were constructed at the 5' and 3' of the *DP1B* gene to make a seed-specific expression cassette for the *DP1B* gene (Table 3). This construct was introduced into soybean somatic embryos using particle bombardment. The transgenic embryonic cells were determined by hygromycin B selection (Finer and McMullen, 1991; Cahoon *et al.*, 1999). Protein analysis demonstrated that *DP1B* can be expressed and the spider draglinelike protein can be accumulated in the soybean embryos. The results indicate that it is possible to produce silklike protein in transgenic soybean seeds and improve the quality and value of the soybean proteins for the fabric industry.

Production of antibodies, enzymes, and vaccines in transgenic plants is a very attractive research area and has made significant progress in the last decade (Biesgen *et al.*, 2002; Schillberg *et al.*, 2003; Warzecha and Mason, 2003). Soybean seeds have special use in this area because they have the capacity to accumulate large amounts of protein. The soybean glycinin G1 promoter can direct high-level expression of GUS protein and a human basic fibroblast growth factor in transgenic soybean seeds. Ding *et al.* (2006) found that the growth factor protein can accumulate to as much as 2.3% of the total soluble seed protein. The G1 promoter expression cassette is useful in expressing recombinant proteins in soybean seeds. Transgenic plants, such as soybean, provide a cheap system for producing valuable proteins. This system is also beneficial because animal viruses or other contaminations can be avoided. However, clearly separating the food and medical products during the development of this technology is important for molecular phytopharming.

2.4.3 Novel fatty acids

In addition to the five common fatty acids, there are more than 200 chemically diverse uncommon fatty acids found in different rare plant species (Van de Loo *et al.*, 1993; Cahoon, 2003). The biosynthesis of these uncommon fatty acids is controlled by specific genes. Research efforts have been focused on isolation of the genes that are associated with novel fatty acid synthesis and the transformation of these novel genes into oilseeds for producing novel oils in the transgenic crops such as soybean (Yadav, 1996; Cahoon, 2003).

One of the unusual fatty acids contains conjugated double bonds, which are different from the double bonds existing in linoleic and α -linolenic acids where the double bonds are separated by methyl groups (Cahoon *et al.*, 1999). Two of the fatty acids with conjugated double bonds are α -eleostearic acid and α -parinaric acid, which are useful in drying oil applications. Cahoon *et al.* (1999) isolated genes encoding δ -12 oleic acid desaturases (also named conjugases) from developing seeds of *Momordica charantia* and *Impatiens balsamina*. These genes are designated *MomoFadX* and *ImpFadX* and were fused together and expressed under seed-specific β -conglycinin promoter and phaseolin terminator (Table 3). Selection of transgenic soybean plants was achieved by hygromycin B with the phosphotransferase gene under control of the CaMV 35S promoter. The constructs were transformed into soybean somatic embryos via particle bombardment (Finer and McMullen, 1991). Transgenic embryos overexpressing the fused genes resulted in accumulation of as much as 17% of α -eleostearic and α -parinaric acids. These results demonstrate the ability to produce fatty acid components of high-value drying oils in transgenic soybean.

Various plant δ -12 oleic desaturases (*FAD2*s) have been identified from plant species and can catalyze the formation of acetylenic bonds, epoxy groups, and conjugated δ -11, δ -13-double bonds from an existing δ -12-double bond in C_{18} fatty acids (Moto *et al.*, 2004; Whittle *et al.*, 2005; Damude *et al.*, 2006). Cahoon *et al.* (2001) isolated two *FAD2* genes, *CoFADX-1* and *CoFADX-2*, from calendic acid-producing *Calendula officinalis*. Vector pKS67 featuring

the seed-specific β -conglycinin promoter and phaseolin terminator (Table 3) was used to express the *CoFADX* genes. Transgenic plant selection is conferred by a hygromycin B phosphotransferase gene under the control of CaMV 35S promoter. The constructs were introduced into soybean somatic embryos by particle bombardment. Expression of either *CoFADX-1* or *CoFADX-2* led to the production of calendic acid in somatic soybean embryos. *CoFADX-2* conferred 22% calendic acid production in the transgenic embryos. Cahoon *et al.* (2006) further demonstrated that soybeans expressing δ -12-oleic acid-related fatty acid conjugases from other plant species significantly accumulate the conjugated fatty acids in phospholipids, which may not be able to be transported and stored in triacylglycerol. Calendic acid, α -eleostearic, and α -parinaric acids are novel conjugated polyunsaturated fatty acids in transgenic soybean that have low oxidative stability which is a superior quality for use as drying oil in coating applications such as paints, varnishes, and inks.

The seed oils of meadow foam (*Limnanthes alba*) and other *Limnanthes* spp. are enriched in the unusual fatty acid δ -5-eicosenoic acid (20:1). This fatty acid has special physical and chemical properties that fit a number of industrial applications. Cahoon *et al.* (2000) isolated the genes encoding an acyl-coenzyme A (CoA) desaturase and fatty acid elongase 1 (*FAEI*) from developing *Limnanthes douglasii* seeds. These genes were co-expressed in soybean somatic embryos under the seed-specific β -conglycinin promoter and phaseolin terminator (Table 3). The CaMV 35S driving the *hygromycin B phosphotransferase* gene was used as a selection marker. These constructs were transformed into soybean embryos by particle bombardment. The fatty acid compositions were measured by the method from Hitz *et al.* (1994). δ -5-eicosenoic acid (20:1) and δ -docosenoic acid increased to as high as 12% of the total fatty acids in the transgenic embryos. These fatty acids have special use in cosmetics, surfactants, and lubricants.

Seed oils of a number of *Asteraceae* and *Euphorbiaceae* species are enriched in 12-epoxyoctadecacis-9-enoic acid (vernolic acid), an unusual 18-carbon δ -12-epoxy fatty acid with potential industrial value. Somatic soybean embryos are enriched in triacylglycerols and provide a model

system for predicting the functions of transgenes in developing soybean seeds (Kinney, 1996). Cahoon *et al.* (2002) isolated a cytochrome P450 enzyme gene classified as *CYP726A1*. To characterize this gene, *CYP726A1* was expressed in somatic soybean embryos under control of the seed-specific β -conglycinin promoter and phaseolin terminator (Table 3). The constructs were transformed into soybean embryos by particle bombardment. Fatty acid analyses indicated that the somatic soybean embryos accumulated vernolic acid and 12-epoxy-18:2 $\delta^{9,15}$. Vernolic acid-enriched seed oils can be used as plasticizers of polyvinyl chloride, a market that is currently served by petroleum-derived compounds or chemically epoxidized soybean and linseed oils (Perdue *et al.*, 1986; Budziszewski *et al.*, 1996). Vernolic acid-containing oils are also useful in adhesives and coating materials such as paint due to the cross linking ability of the epoxy group (Perdue *et al.*, 1986). Furthermore, vernolic acid can be used as a precursor of monomeric components of nylon-11 and nylon-12 (Ayorinde *et al.*, 1997). Cahoon and Kinney (2004) isolated two genes encoding divergent forms of δ -12-oleic acid desaturase, designated *DsFAD2-1* and *DsFAD2-2*, from developing *Dimorphothea sinuata* seeds and expressed them in soybean. *DsFAD2-1* and *DsFAD2-2* were expressed under the β -conglycinin promoter and phaseolin terminator in the vector pKS67 (Table 3). The fused genes of *DsFAD2-1* and *DsFAD2-2* were also expressed under the β -conglycinin promoter and phaseolin terminator in vector pKS67 (Table 3). These constructs were introduced into soybean somatic embryos by particle bombardment. To test the genes simultaneously, co-transformation was also carried out as described by Finer and McMullen (1991) (Cahoon *et al.*, 2000). Transgenic embryos were selected by hygromycin resistance conferred by the marker gene for HPT in pKS67. Expression of *DsFAD2-1* resulted in significant accumulation of the *trans*- δ -12 isomer of linoleic acid (18: 2- $\delta^{9cis,12trans}$) rather than the more typical *cis*- δ -12 isomer in soybean somatic embryos. Expression of *DsFAD2-2* alone resulted in trace amounts of the *cis*- δ^{12} isomer of dimorphecolic acid (9-OH-18:2- $\delta^{9cis,12cis}$). Co-expression of both genes resulted in accumulation of dimorphecolic acid in soybean embryos.

Overexpression of *FAD3* gene in soybean significantly increased the linolenic acid from 10%

in the control to 50% in the transgenic soybean line (Cahoon, 2003). The transgenically modified soybean oil has low oxidative stability, which is a desirable property of drying oil used in coating applications such as paints, inks, and varnishes. The seed oil of flax (*Linum usitatissimum*) contains a high level of linolenic acid, 45–65% of the total fatty acids, which also makes it useful as drying oil. Vrinten *et al.* (2005) isolated a flax gene *LuFAD3A* encoding microsomal desaturase. This gene is capable of desaturating linoleic acid and can recover the high linolenic acid traits when expressed in low linolenic-acid flax. The flax 2S storage protein conglycinin promoter was used to overexpress *LuFAD3A* gene and the construct was transformed into flax by *A. tumefaciens* strain GV3101. The transgenic flax seeds contained a high level of linolenic acid. *FAD3*-like genes have been isolated from other plant species and are useful gene sources for engineering soybean to produce high levels of linolenic acid.

Transgenic technology can significantly improve soybean oil and protein compositions to develop desirable soybean-based products. The challenge is the productive level and the potential negative impact on the plants (Kinney *et al.*, 2001). Highly active and specific novel desaturases can be achieved by gene shuffling technology (Castle *et al.*, 2004). Expression of novel and diverse desaturases in soybean may enable soybean seeds to be used as a factory for producing valuable soybean oils for various industrial usages.

2.5 Regulations of Transgenic Soybean Plants

All of the regulations pertaining to transgenic plants apply to transgenic soybeans. As illustrated in Section 3.2, transgenic soybean plants with high oleic acid or herbicide resistance traits were subjected to extensive field trials and regulatory studies before their commercialization. Release of all transgenic soybeans is regulated by various regulatory authorities in different countries. In the United States, USDA Animal and Plant Health Inspection Service (USDA-APHIS) permits are required for shipping transgenic soybeans across state lines, performing

greenhouse experiments, and for field evaluations (<http://usbiotechreg.nbii.gov/roles.asp>). All transgenic products require approvals from the EPA (<http://www.epa.gov>) and the FDA before commercialization. These approvals require robust data demonstrating that novel transgenic products are safe for human consumption, safe for the environment, and do not negatively impact nontarget organisms. Field experiments involving transgenic plants are highly regulated by federal and state laws as well as institutional biosafety committees (IBCs). IBCs have been established under the National Institute of Health (NIH) guidelines to provide local review and oversight of transgenic research. For greenhouse research with transgenic plants, NIH has guidelines at four physical containment levels (http://www.isb.vt.edu/greenhouse/green_man.section3.htm) to prevent the transfer of recombinant DNA from transgenic organisms in greenhouse experiments to organisms outside the greenhouse. Regulatory procedures have also been developed in countries other than the United States. In Europe, the European Economic Community (EEC) controls the release of transgenic plants into the environment. Developing countries like China and India are also developing regulatory procedures (Huang and Wang, 2002; Huang *et al.*, 2002; Manjunath, 2005). UNIDO/UNEP/WHO/FAO is contributing to the development and application of common procedures for developing countries (UNIDO, 1991). The Rio de Janeiro Agreement (Taylhardat and Zilinskas, 1992) intends to foster the development of an international set of guidelines on safety in biotechnology.

As summarized in Table 3, soybean scientists are developing various transgenic traits to improve soybean productivity, increase nutritional value, and expand soybean's industrial uses. Currently only RR soybeans and high oleic soybeans are available on the soybean market. *Bt* soybeans are currently at the field-testing stage (Macrae *et al.*, 2005), and novel herbicide resistant products are being developed (Castle *et al.*, 2006). As illustrated by RR soybeans and high oleic soybeans, transgenic crops are becoming more popular each year and unquestionably more exciting transgenic soybean products will undergo regulatory approval and will be on the market in the near future.

3. FUTURE PERSPECTIVES

3.1 Expected Transgenic Products

RR soybean was the first transgenic soybean product that was developed by Monsanto and commercialized in 1996. It went from 17% of US soybean acreage in 1997 to 68% in 2001 and 89% in 2006 (<http://www.ers.usda.gov>). Global production of herbicide-tolerant soybean during the 2006 growing season was estimated at 133 million acres in nine countries including the United States, Argentina, Brazil, Paraguay, Canada, Uruguay, Romania, South Africa, and Mexico. (<http://www.monsanto.com/monsanto/content/investor/financial/reports/2006/Q32006Acreage.pdf>). More than 50% of them (71 million acres) were planted in the United States, followed by Argentina (37 million acres) and Brazil (19 million acres) (Ash *et al.*, 2006). The widespread acceptance of RR soybean is significantly promoting the development of various transgenic traits in soybean.

The second transgenic soybean product to receive clearance for market is the high oleic soybeans developed by DuPont. The high oleic level in soybean can provide health benefits to consumers (Kinney and Knowlton, 1998; Buhr *et al.*, 2002) as well as better properties for use in industrial applications such as biodiesel, lubricant formulations, and polyol (Cahoon, 2003).

According to the field test release permits database authorized by USDA-APHIS, two major industrial companies, DuPont and Monsanto, are the leaders in developing soybean biotech traits including yield enhancement, altered maturity, altered feed property, altered flavonoid level, altered fatty acid metabolism, ω -3 fatty acids, altered oil profile, altered amino acid composition, altered carbohydrate metabolism, protein quality, altered starch metabolism, altered seed composition, altered cell wall, altered fiber, drought tolerance, cold tolerance, high temperature tolerance, salt tolerance, *Sclerotinia* resistance, nematode resistance, lepidoptera resistance, aphid resistance, glyphosate tolerance, dicamba tolerance, PPT tolerance, sulfonylurea tolerance, nitrogen utilization efficiency, and phytate reduction. There are also great efforts in academia (<http://www.isb.vt.edu/cfdocs/fieldtests1.cfm>). We will highlight a few promising future products with quality output

traits and agronomic input traits as well as industrial usages.

The second generation of transgenic soybean products will likely be Optimum™ GAT™ and RReady2Yield™ soybeans for herbicide resistance, *Bt* for insect resistance, and ω -3 and high oleic for healthy oils. The optimized GAT in combination with resistance to sulfonylurea herbicide confers dual herbicide resistance with two modes of action for weed management. The soybean product Optimum™ GAT™ is expected to be on the market in 2008 (<http://www.pioneer.com/pipeline/pipeline.pdf>) (Soper *et al.*, 2003). The lead event of RReady2Yield™ soybean (www.monsanto.com) was confirmed in April 2005, and this new trait is expected to deliver better yield. *Bt* soybeans are in field trials and initial results show significant yield protection. ω -3 soybeans are also under field evaluations and preliminary data show that current transgenic events have improved agronomics and emergence over earlier events (www.monsanto.com). Products with stacked traits, such as herbicide and insect resistances or herbicide resistance and a modified oil trait, could also possibly be on the market in 5–10 years.

As indicated in Table 3 and the current APHIS permit database, biotechnologists are developing various agronomic input and quality output traits as well as industrial products in transgenic soybeans. A few potential long-term products are listed here.

1. Quality output traits: High linolenic acid, high lysine and high sulfur amino acid, ω -3, reduced phytate, modified flavor, vitamin E, LCPUFA, and modified protein compositions.
2. Agronomic traits: High yield, nematode resistance, virus resistance, drought tolerance, and fungal resistance.
3. Industrial uses: High oil, novel fatty acids, and special oils for industrial uses such as biodiesel.

The ultimate purpose of improving resistance or tolerance to biotic and abiotic factors is to increase the productivity of harvestable yield. Yield is the most complex trait, which is the result of various growth and developmental processes. However, accumulated evidence in model plants indicates that crop yield can be improved by manipulating genes that regulate biological processes such as photosynthesis, starch biosynthesis, nitrogen

utilization, plant architecture, and signaling pathways (Good *et al.*, 2004; Camp, 2005; Raines, 2006). Soybean research, such as photosynthesis and nitrogen utilization, could benefit from advances in these areas.

Crops are separated into two classes according to their photosynthetic carbon assimilation pathway. The most common class, known as C_3 includes major crops such as rice, wheat, and soybean. The first product of photosynthesis in C_3 plants is 3-phosphoglycerate, a three carbon compound. It is produced in the Calvin cycle by ribulose 1,5-bisphosphate carboxylase dikinase (Rubisco), which has both carboxylase and oxygenase activities. Its carboxylase activity assimilates CO_2 and produces oxygen in photosynthesis, and the oxygenase activity generates CO_2 in photorespiration. Competitive inhibition of CO_2 fixation by O_2 at the Rubisco active site can result in a loss of up to 50% of the carbon fixed during photorespiration (Ogren, 1984). The other photosynthetic class is known as C_4 plants. During the evolution of higher plants, C_4 crops such as maize have developed a strategy to release CO_2 at the site of the Rubisco, thus concentrating CO_2 and increasing the ratio of Rubisco carboxylation/oxygenation (Leegood, 2002). This mechanism prevents major losses of CO_2 during photorespiration and increases the efficiency of water and nitrogen use compared to C_3 crops. The first step in the C_4 cycle is the carboxylation of phosphoenolpyruvate by phosphoenolpyruvate carboxylase, which produces oxaloacetate, a four carbon compound. In general, C_4 crops have better photosynthesis capacity and produce more biomass under water stress conditions compared to C_3 crops (Häusler *et al.*, 2002; Miyao, 2003). All of the enzymes and transporters involved in the C_4 pathway also exist in C_3 plants. The main differences between the two classes of crops are the activity levels, functions, and localizations of the enzymes involved. To improve the C_3 crop photosynthesis capacity, scientists have pursued overexpression of C_4 enzymes in C_3 plants (Häusler *et al.*, 2002; Miyao, 2003). Since photosynthesis and the downstream carbon and nitrogen metabolisms mainly occur in the mesophyll cells in C_3 plants, transgenes were targeted to these cells. The enzymes evaluated in transgenic plants include phosphoenolpyruvate carboxylase, malic enzymes, malate dehydrogenase,

phosphoenolpyruvate carboxykinase, pyruvate/orthophosphate dikinase, and metabolite transporters. These approaches have mainly been carried out in model plants such as tobacco and rice (Häusler *et al.*, 2002). Ku *et al.* (2001) reported that co-expression of both phosphoenolpyruvate carboxylase and pyruvate/orthophosphate dikinase in rice could increase photosynthetic capacity up to 35% and grain yield by 20% compared to the nontransformed plants. These preliminary observations are to be confirmed in advanced generations. Another approach is to directly improve Rubisco activity. Scientists at Verdia-Pioneer-DuPont (Zhu *et al.*, 2005) have generated a heat-tolerant version of the Rubisco activase by gene shuffling technology. Transgenic *Arabidopsis* plants expressing this optimized Rubisco activase showed significantly improved photosynthetic performance and leaf growth compared to the nontransformed control plants. Other approaches have been reviewed recently (Pellny *et al.*, 2004; Sakamoto and Matsuoka, 2004; Camp, 2005; Raines, 2006). The technology developed with model plants may be used to enhance soybean's photosynthetic performance. The enhanced level of photosynthetic oxygen release may increase lipid synthesis and storage in developing seeds (Rolletschek *et al.*, 2005).

Nitrogen fixation symbiosis on the roots of leguminous plants, such as soybean, reduces the need for nitrogen fertilizer. This symbiosis includes complex interactions between host roots and specific rhizoidal bacteria resulting in the formation of nodules in which the bacteria fix nitrogen. Genetics and genomic studies have significantly advanced our understanding of the mechanisms that control nodulation and nitrogen fixation. Genes with potential to improve nitrogen use efficiency have been discovered and evaluated in model plant systems as recently reviewed (Good *et al.*, 2004; Pauly *et al.*, 2006; Stacey *et al.*, 2006). A number of important factors involving various signaling pathways of nodule formation have been discovered, including soybean genes. Soybean apyrase is an early nodulin that has important roles in nodule formation and can increase nodulation in *Lotus japonicus* (McAlvin and Stacey, 2005). ENOD40 is an important nodulin in *L. japonicus* (Kumagai *et al.*, 2006). These examples indicate that the capacity for nitrogen

fixation in legumes such as soybean could be improved by transgenic manipulation of important nodulins.

Biotechnology has opened a bright future for improving soybean traits. Biodiesel has great positive benefits on the economy and environment (Hill *et al.*, 2006). The increasing demand for soybean oils as a renewable biofuel resource will significantly promote investment in and the advancement of soybean research. Transgenic soybean products will help to meet this demand. However, unintended effects can occur in the transgenic soybeans. It is important to keep "risk" sense in mind during research and product development as well as marketing.

3.2 Risk Assessment

3.2.1 Food safety concerns and issues

Assessing the occurrence and significance of unintended health effects using a range of toxicological, metabolic, and epidemiological sciences is necessary to fully understand the effects of transgenic plants in the environment. Current safety assessments prior to commercialization focus on comparing the transgenic food with its conventional counterpart (a near-isogenic line or variety) to identify unique components. Typically, these comparisons are made on the basis of proximate analysis—an analytical determinant of major classes of food components as well as nutritional components, toxins, toxicants, antinutrients, and any other characterizing components. In addition to compositional comparisons, agronomic comparisons have been routinely conducted as part of the line selection phase in the development of transgenic crops (Chassy *et al.*, 2004). Animal feeding trials are also used to compare the nutritional qualities of a transgenic crop with its conventional counterpart. Any adverse effects on the health of the animals indicate the possible existence of unexpected alterations in the transgenic crop that could adversely affect human health if consumed.

Postmarket stewardship is an approach to verify premarket screening for unanticipated adverse health consequence from the consumption of transgenic food. This approach holds promise

in monitoring potential effects, anticipated and unanticipated, of transgenic foods that are not substantially equivalent to their conventional counterparts or that contain significantly altered nutritional and compositional profiles. To help ensure acceptance, soybeans derived through transgenic breeding must be developed while following stringent safety and regulatory guidelines established by industry and government agencies. These guidelines must be followed from product concept to postmarket stewardship (Soper *et al.*, 2003).

The safety of high oleic soybeans for use as food and livestock feed was established based largely on the fact that there were no new proteins present in these soybean lines. It was determined that the allergenic potential of the high oleic soybeans was the same as for conventional soybeans. The nutritional equivalence of the transgenic soybeans compared to conventional soybeans was demonstrated by the analyses of key nutrients, including proximates (e.g., protein, fat, fiber, ash, and carbohydrates), amino acid and fatty acid composition, as well as antinutrients. High oleic soybean oil contains approximately 10% saturated fats, greater than 80% oleic acid, and low levels of polyunsaturated fatty acids (approximately 2% linoleic acid and 3.5% linolenic acid). Trace amounts (0.5%) of a linoleic acid 9,15 isomer were also detected, which, while absent from nonhydrogenated soybean oil, is present at similar levels in butterfat, and is often found at considerably higher levels (typically 1–3%) in partially hydrogenated vegetable oils. The equivalence of high oleic soybeans to conventional soybeans was confirmed in feeding studies with pigs and broiler chickens. Soybean meal from high oleic soybeans was nutritionally equivalent to processed soybean meal derived from the conventional soybeans (Kinney and Knowlton, 1998; Chassy *et al.*, 2004).

High oleic soybeans are a value-added commodity. These premium soybeans are grown under contract to preserve the identity of high oleic soybeans from the point of planting through delivery of seed to the processing plant. Other than this, management and production practices for growing high oleic soybeans are much the same as growing any regular variety of soybeans.

3.2.2 Environmental issues

High oleic acid soybean lines were tested in field trials in the United States and Canada. Data collected from these trials demonstrated that these lines did not differ from conventional soybeans in agronomic characteristics including seed production and susceptibility to diseases and insects. These tests also demonstrated that the transformed lines did not exhibit weedy characteristics or negatively affect beneficial or nontarget organisms, and were not expected to have an impact on threatened or endangered species.

There has been some concern whether the transgenic herbicide resistance trait would flow into weeds. To date all instances of weeds becoming resistant have resulted from the plant evolving its own biochemical mechanism and not by acquiring resistance genes from the crop. Nonetheless, in certain circumstances it would be possible for herbicide resistance genes to flow from the crop to weeds. The most important variable affecting gene flow is the degree of relatedness between the crop and the weed, making gene flow only possible if close relatives are growing near the crop. As a result, the possibility of gene flow depends first and foremost on the presence of weedy relatives in the environment.

Soybean does not have any weedy relatives with which it can crossbreed in the continental United States and Canada. Cultivated soybean can naturally cross with the wild annual species *G. soja*; however *G. soja*, which occurs naturally in China, Korea, Japan, and the former USSR, is not naturalized in North America. Additionally, soybean plants are almost completely self-pollinated, and reproductive and growth characteristics were unchanged by the genetic modification resulting in these high oleic acid soybean lines. It was, therefore, concluded that the potential for transfer of the trait for high oleic acid from the transgenic line to soybean relatives through gene flow (outcrossing) was negligible in managed ecosystems, and that there was no potential for transfer to wild species in Canada and the continental United States.

Soybean meal is primarily used for animal feed. One of the major challenges facing animal production is the prevention of environmental

pollution from animal production facilities. Environmental pollution concerns have focused primarily on phosphorus, nitrogen, and malodor. In the United States, the EPA as well as state natural resources and conservation agencies, have enacted regulations for the application of animal waste to land, mainly concerning the loading rate of phosphorus and nitrogen onto soil as well as the malodor abatement. The regulatory pressures of nitrogen excretion and malodor abatement present costs associated with feed ingredients that contribute to excess nitrogen excretion or malodor production. Failure to address these issues will negatively affect animal production in the United States and other countries (Kerley and Allee, 2003). Environmental opportunities associated with lowering the levels of nitrogen and phosphorous manure components generated per animal fed may be achieved through biotechnology. Nitrogen can be addressed by improving the amino acid balance, as well as the extent to which soybean meal protein is digested. Phosphorus can be addressed by increasing the extent to which the digestible phosphorus is present in the meal and productively utilized by the animal.

The transgenic high oleic soybeans are a good example of how biotechnologists can develop a safe and useful product, however, this is not always the case. Unintended effects in transgenic crops have been reported (Chassy *et al.*, 2004). For example, the original purpose of expressing glucose oxidase in cotton and tobacco was to engineer plants with enhanced resistance to fungal diseases (Murray *et al.*, 1991). However, in addition to reducing fungal infection the oxidase caused phytotoxic effects in the transgenic plants. Unintended effects have also been observed in conventional breeding programs (Chassy *et al.*, 2004). Therefore, both conventional and transgenic breeding approaches require risk assessment. To meet the challenge, improved and novel technologies are required.

3.3 Technologies that Improve Transgenic Breeding

Development of a transgenic trait in soybean requires a trait gene, a proper promoter, a method of transferring the promoter-gene-terminator unit

into the soybean genome, evaluation of the trait gene in the greenhouse and field, and then breeding the transgene unit into elite lines for product development. Improved and novel technologies are required to accelerate the discovery of trait genes and promoters, improve gene efficacy, express transgenes in desirable patterns, and efficiently stack and transfer the transgenes into elite lines. This section describes a few technologies that have the potential to promote the development of desirable transgenic traits in soybeans.

3.3.1 Genomics

Genomics is an emerging tool in biotechnology for the effective study of the function and structure of genes for almost all organisms. Although single-gene and single-investigator studies will continue to provide detail and resolution to our understanding of biological processes, the high-throughput discovery tools of genomics will become the dominant tools for identification and expression of genes for desired trait development (Shoemaker *et al.*, 2003). The genomes of soybean and other species hold a vast resource of gene blueprints that will aid the development of desired traits such as pest resistance, higher yield, and better grain composition. The knowledge-based tools also help to develop gene markers for trait selection or trait solutions (Soper *et al.*, 2003).

The soybean has a rich repertoire of genomic tools and resources that include a vast EST collection, a densely populated genetic map, developed physical maps, microarray resources, and a relatively efficient transformation system. It also has a large and active research community.

A genome-wide physical map was constructed from more than 78 000 BAC clones. This map consists of approximately 2900 contigs. The total contig length exceeded the predicted size of the soybean genome. More than half of the length of the physical map was anchored to the genetic map using RFLP and SSR markers (Wu *et al.*, 2004). A second physical map of the soybean genome was recently constructed using Williams 82 cultivar, chosen as the model genotype by the soybean community (Warren, 2006). A total of 96 524 fingerprints were generated from two independent BAC libraries, referred to as UM-BstyI and ISU-*Hind*III, utilizing the

high information content capillary fingerprint (HICF) method. The map consists of a total of 1880 fingerprint contigs. Molecular markers were associated with specific contigs by RFLP hybridization, overgo oligo hybridization, RFLP hybridization or SSR screening of BAC DNA pools. This resulted in 4015 clones and 715 contigs with associated markers. One of many potential applications of genome physical maps is to determine locations of transgenes within the genome.

Soybean has amassed more than 300 000 ESTs representing over 80 different cDNA libraries sponsored by the soybean commodity boards (North Central Soybean Research Program (NCSRP) and United Soybean Board (USB)) (Shoemaker *et al.*, 2002). The cDNA libraries giving rise to those ESTs represent a wide range of organs, developmental stages, genotypes, and environmental conditions. This resource provides a great deal of information on differences in gene expression of members of multigene families (Granger *et al.*, 2002). The soybean EST collection provides a large resource of publicly available genes and gene sequences and provides valuable insight into structure, function, and evolution of this model crop legume (Shoemaker *et al.*, 2003).

Genome sequencing is fundamental to understanding the genetic composition of an organism. Generation of whole-genome sequences of soybean is lacking. A prerequisite to reaching this goal is to understand the organization, complexity, and distribution of the gene space of an organism, including the topography of its repetitive sequences. Genomic sampling of nearly 2700 DNA sequences from more than 600 mapped loci (Marek *et al.*, 2001) and 237 000 BAC-end sequences obtained from the Better Bean Initiative (USB) has provided a glimpse of the composition and general structure of the soybean genome. These sequences will be instrumental in defining soybean gene space and in creating a soybean repeat database useful for whole-genome sequencing efforts (Shoemaker *et al.*, 2003). Recently, the Joint Genome Institute of the Department of Energy announced their intention to sequence the whole genome of soybean. The initial plan is to carry out a whole genome shotgun up to 4× coverage to be completed within 2 years.

Using these EST and genomic sequences, the soybean community has developed a large number

of molecular markers (Section 1.4). MAS for native traits has been routinely practiced in soybean. With an increasing number of transgenic traits in soybean, marker-assisted backcrossing will be the next major application of molecular markers. Backcrossing is often used to incorporate transgenes into elite germplasm. In traditional backcross programs, a gene's presence and absence in a backcross individual is often determined by a time-consuming phenotypic assay. Moreover, background selection for the recovery of recurrent parent genome is also a lengthy process. Without selection, Young and Tanksley (1989) found lengths up to 51 cm of the segment attached to a resistance gene after six backcross generations in tomato. With the development of high-density molecular linkage maps in soybean, it became possible to select individuals that not only carry transgenes but also are homozygous for the recurrent parent alleles at the large portion of markers. Using molecular markers in background selection can reduce both the number of backcross generations needed and the size of linkage drag (Frisch and Melchinger, 2000), and thus improve the efficiency of transgenic product development.

Functional genomics is a useful approach for accelerating the studies of function and structure of genes. High-density expression arrays containing 18 000 cDNAs arrayed on a filter have been developed (Vodkin *et al.*, 2002) along with microarray technology. Serial analysis of gene expression (SAGE) captures short 10–20-nucleotide “tags” near the 3' end of individual mRNA molecules. This technology has been used to accurately estimate expression levels in the mRNA source tissue based on the frequency of tag appearances in the library. Initial analysis from 20 SAGE libraries in soybean has resulted in 132 992 SAGE tags, of which 40 121 are unique (Shoemaker *et al.*, 2003, 2004). The applications of microarray technology to soybean are enormous. The future of functional genomics research will include arrays that will distinguish gene family members. Phenotypical functional genomics systems via gene knockout systems are also needed in soybean (Shoemaker *et al.*, 2003). In soybean, transposon tagging projects, viral-induced gene silencing systems, and TILLING (targeted induced local lesions in genomes) populations are under development and will become useful tools for phenotypical

functional genomics. Crop genomics promise a new era of yield maximization through genetic improvement and optimized crop management (Johnson, 1987; Somerville and Somerville, 1999; Huang *et al.*, 2002). Most agronomic and quality traits are genetically complex (Stuber *et al.*, 2003) and often show complex interactions between genotype and environment. Various molecular models such as Decision Support System for Agrotechnology Transfer (DSSAT) (Jones *et al.*, 2003) and Agricultural Production Systems Simulator (APSIM) (Keating *et al.*, 2003) have been reported for linking genetic organizations and whole-organism phenotypic expression. Recently, Messina *et al.* (2006) reported a gene-based model (CROPGRO-Soybean) of simulating soybean development and yield responses to environment. Their model indicates that gene-based approaches can effectively use agricultural genomics data for cultivar performance prediction.

The rich genomic resources available for soybean make it a model legume crop. The gene discovery stemming from structural and functional genomics research in soybean will certainly lead to discovery of trait genes for developing new products and varieties with improved nutritional and agronomic characters. A number of desaturase genes were discovered by EST sequencing and bioinformatics searches and showed potential for novel soybean products (Cahoon, 2003). These are examples of how genomic tools accelerate gene discovery. Functional genomics data from other crops are available and comparative analysis of the genomics data can lead to the discovery of new trait genes (Windsor and Mitchell-Olds, 2006).

3.3.2 Promoter technology

Promoters have critical roles in successful transgenic crop improvement. A broad spectrum of promoters that can regulate the temporal and spatial expression patterns of a transgene when needed can be an effective tool to fine-tuning the transgene expression. Promoters can be divided into three categories: constitutive (with viral and plant origin that drive constitutive expression), tissue- or temporal-specific (fruit, seed, tubers, flowers, pistils, anther and pollen, roots, root

nodules, leaves, and stem tissue), and inducible promoters (their activities can be regulated by biotic and abiotic signals).

The most common promoters used for constitutive overexpression are derived from plant virus sources, such as the CaMV 35S promoter (Odell *et al.*, 1985). Details of other virus promoters can be found in the review by Potenza *et al.* (2004). Concerns of using the virus promoters include the perception of risk to human health due to the infective viruses (Ho *et al.*, 1999; Hull *et al.*, 2000) and transcriptional gene silencing (TGS) of methylation-dependent and methylation-independent inactivation of the transgene and promoter (Scheid *et al.*, 2002). Endogenous plant promoters are used regularly to drive high constitutive levels of transgene expression; actin and ubiquitin promoters are the common ones that are used heavily in the plant biotechnology. Actin is a fundamental cytoskeletal component that is expressed in nearly every plant cell (McElroy *et al.*, 1991; An *et al.*, 1996). One of the most popular promoters used for transformation is the maize ubiquitin 1 promoter (Christensen *et al.*, 1992). Synthetic SCP1 and UCP3 are strong constitutive promoters in dicot crops (Lu *et al.*, 2000).

Constitutive expression can be problematic when a transgene is overexpressed at the wrong time in biological development in tissues where it is not normally expressed, or at very high levels. It can have unexpected consequences on plant growth and development as well as the environment (Potenza *et al.*, 2004). The development of tissue-specific promoters that are activated precisely when and where they are needed is ideal for developing value-enhanced crops. For example, the strong soybean seed-specific promoter β -conglycinin has been heavily used to improve oil and protein compositions in transgenic soybean seeds as seen in Table 3 (Kinney and Knowlton, 1998; Cahoon *et al.*, 2001; Buhr *et al.*, 2002; Herman *et al.*, 2003; Sato *et al.*, 2004). Expression of transgenic proteins only in the nonedible parts of the plant with the use of tissue-specific promoters may help to ease the public's fears of consuming foods produced from transgenic soybean plants. Potenza *et al.* (2004) listed plant tissue-specific promoters including flower, pollen, pistil, anther, seed, tuber/storage organ, green tissue, fruit, nodule, and root.

In plants, various types of stress, both biotic and abiotic, induce a large number of genes. Pathogens, such as nematodes, can induce promoter activity (Gheyson and Fenoll, 2002). For example, UCP3 and SUP promoters were induced in the SCN nematode feeding sites, whereas SCPI promoter activity was significantly repressed (Hu and Lu, 2006). When a plant is under abiotic stress, genes are mobilized for defense and repair. For example, the promoter for the potato PI II gene also directs low constitutive expression, but was induced to high levels by wounding and methyl jasmonate when transformed into rice (Xu *et al.*, 1993). Many genes induced by abiotic stress contain two distinct cis-acting elements within their promoters. They are a dehydration-responsive element, or DRE (TACCGACAT) (Yamaguchi-Shinozaki and Shinozaki, 1994), and an abscisic acid-responsive element, or ABRE (ACGTGG/TC) (Bonetta and McCourt, 1998). Tissue-specific promoters are still dependent on the plant and the expression pattern of endogenous transactivating factors. Sometimes, a characterized heterologous promoter might act differently when placed in a different genus, species, or even cultivar of a plant. Inducible (and repressible) promoter systems using both endogenous and exogenous components could help to switch transgene expression on or off at precisely the right time.

Most inducible/repressible promoter systems are two-component systems with molecular “on-off” switches that vary in complexity. They include a transcription factor gene that responds to a chemical, binds to a “target” promoter that contains the transcription factor’s cis-acting element. The target promoter is fused to the transgene of interest and the binding of the transcription factor modulates its expression (Potenza *et al.*, 2004). Chemicals that are used to regulate transgene expression include the antibiotic tetracycline (Weinmann *et al.*, 1994; David and Perrot-Rechenmann, 2001), the steroids dexamethasone and estradiol (Martinez *et al.*, 1999; Bruce *et al.*, 2000; Zuo *et al.*, 2000, 2002), copper (Mett *et al.*, 1993), ethanol (Roslan *et al.*, 2001), the inducer of pathogen-related proteins benzothiadiazol (Gorlach *et al.*, 1996), herbicide safeners (De Veylder *et al.*, 1997), and the insecticide methoxyfenozide (Unger *et al.*, 2002). Systems that are suitable for field application are

particularly useful for experimental systems and have potential applications in plant biotechnology.

An ideal inducible gene expression system should have a low basal level of expression, be highly inducible, have a high dynamic range for inducer concentration, involve a rapid response, switch off after the removal of the inducer, and have an inducer of low toxicity and high specificity that is not found in plants (Padidam, 2003). Although the precise time and control of the transgene expression using the inducible promoter system can be achieved, the drawbacks for these inducible systems are the toxicity of the chemical or inducers used, and their tendency to be regulated by the products of their metabolism (Potenza *et al.*, 2004). For product application, the use of environmentally safe chemical inducers is critical. Multiple-inducible systems that can regulate several genes or pathways independently will be of great value to applications in proteomics and systems biology.

3.3.3 RNA interference

As we learned from the virus resistance (Section 2.2.3) and oil modification (Section 2.3.1) sections, RNAi is a useful technology for silencing endogenous genes to achieve desired traits. Hairpin-mediated RNAi has advantages over the antisense and co-suppression or mutation-based reverse genetic methods in terms of silencing stability and efficiency (Kusaba, 2004). RNAi pathways and mechanisms in plants are much clearer now (Wang and Metzlaff, 2005; Meyers *et al.*, 2006), and it will exhibit greater power in developing transgenic traits in soybeans as we move forward. For example, RNAi technology can facilitate broad-spectrum virus resistance (Prins, 2003) and nematode resistance (Hussey and Huang, 2006) with enhanced durability. RNAi in combination with a specific promoter can express transgenes in a more desirable pattern for trait development. In addition, RNAi takes an important role in functional genomics research and facilitates trait gene discovery (Travella *et al.*, 2006).

Although RNAi is in general sequence specific, unintended effects have been reported (Scacheri *et al.*, 2004). Therefore, the gene fragment in the hairpin constructs should be target gene-specific and have no side effects on any other

soybean genes. The soybean gene sequences and bioinformatics tools can be employed to achieve this objective before testing the constructs in soybean tissues.

3.3.4 Gene shuffling

The term “gene shuffling” covers a range of molecular techniques or processes that feature the rapid shuffling and recombination of the DNA sequences that make up a desirable protein function or a desirable protein complex. Gene shuffling improved on this process by using recombination to combine favorable mutations and to remove deleterious mutations from the population of evolving proteins (Stemmer, 1994).

Protein improvement can be achieved through a single or recursive round of shuffling. Most likely, the desired result is obtained from recursive rounds of shuffling in which the best progeny from the previous round of DNA shuffling are used as parents for subsequent rounds. DNA shuffling using single starting genes enabled dramatic improvement in protein properties when compared to previous methodologies of DNA recombination (Lassner and Bedbrook, 2001). The rate of random mutagenesis can be controlled by adjusting reaction conditions or by using different DNA polymerases (Zhu *et al.*, 2005), thereby controlling the amount of new diversity introduced at each generation of protein improvement. DNA shuffling has not been limited to the improvement of single genes, but has also been applied to improving pathways (Lassner and Bedbrook, 2001). Multigene shuffling using recombined natural diversity associated with different starting genes, rather than recombining random mutations associated with single gene shuffling, is an effective approach for direct molecular evolution for plant improvement. The relative success of multigene shuffling attributed to several factors was elucidated by Lassner and Bedbrook (2001). First, natural diversity's proven functionality leads to the recombination of functional sequences allowing the screening of more functional gene variants. Second, multigene shuffling causes sequence block exchanges, yielding chimeras that have greater divergence. Multigene shuffling results in the sampling of a much greater area of sequence space.

Several examples including GUS as a reporter gene, carotenoid biosynthesis pathway to produce antioxidants, triazine detoxification for herbicide tolerance, and *Bt* genes for insect resistance, demonstrated the effectiveness of the gene shuffling for plant improvement (Lassner and Bedbrook, 2001). Recently, a new mechanism for detoxifying glyphosate *in planta*, deactivation by acetylation, was developed (Castle *et al.*, 2004). The GAT gene derived from a naturally occurring soil bacterium (*Bacillus licheniformis*) was shuffled for 7–11 rounds to optimize both the enzyme's acetylation efficiency and its specificity before incorporating the gene into plants including soybean (Castle *et al.*, 2004; Siehl *et al.*, 2005).

The technology allows plant molecular biologists to improve genes and pathways in a manner that mimics the breeding procedures used by plant breeders. As in plant breeding, desirable characteristics from otherwise undesirable or uncharacterized parents can be bred into progeny through backcrossing for several generations. Backcrossing, a tool used by plant breeders to introduce novel traits into high quality breeding lines, can also be used in molecular breeding projects to remove unwanted and unnecessary mutations. Gene shuffling is becoming a highly effective tool for creation of desirable input or output traits for soybean improvement.

3.3.5 Transformation efficiency and plastid transformation

Transformation efficiency is the outstanding bottleneck of soybean biotechnology. As other legumes, soybean has been regarded as recalcitrant to transformation. Only a few specific genotypes can be regenerated *in vitro*, however, cultivated varieties are rarely amenable to regeneration, with an even lower transformation frequency (Somers *et al.*, 2003). A list of the literature on the regeneration and transformation of soybean globally is compiled at the web site: <http://www.cropsoil.uga.edu/soy-engineering/index.html>. Since the first transgenic soybean plants were produced via *Agrobacterium* (Hinchee *et al.*, 1988) and particle gun bombardment (McCabe *et al.*, 1988), the transformation systems have been improved (Zhang *et al.*, 1999; Xing *et al.*, 2000; Clemente and Klein, 2004; Olhoft

et al., 2004). Although soybean transformation efficiencies are consistently greater than 5% in Jack (Soper *et al.*, 2003), the frequency is quite low compared to corn (20–60%). Clemente and Klein (2004) discussed the current issues and strategies for improving soybean transformation efficiency. As described in Section 2.1, a number of factors impact the transformation efficiency including tissue type, culture medium, genotype, wounding, and temperature. Combination of particle bombardment and *Agrobacterium* methods is worth further investigation. Any factors that can increase proliferation can enhance the transformation rate. Gene transfer directly into meristematic cells by particle bombardment or *Agrobacterium* is encouraging since it skips the tissue culture steps. Optimizations of the particle bombardment conditions and identification of more efficient *Agrobacterium* strains will likely enhance the transformation productivity.

Plastid (or chloroplast) transformation was first successfully achieved in 1990 (Svab *et al.*, 1990) and is routine in tobacco (Svab and Maliga, 1993; Staub and Maliga, 1995b). It has been demonstrated in a limited range of other species (Daniell *et al.*, 2005). Particle bombardment is most often used for chloroplast transformation, although tobacco protoplasts can incorporate foreign DNA into their plastids (Golds *et al.*, 1993). Chloroplast transformation offers certain advantages, including the ability to precisely deliver genes into predetermined locations in the plastid genome by homologous recombination, high levels of transgene expression due to the presence of multiple copies of the plastid genome in each cell, consistent expression between independent transgenic events, and the lack of transgene transmission through pollen. Multiple genes can be inserted into plastids as polycistrons (Staub and Maliga, 1995a, b; Quesada-Vargas *et al.*, 2005); which could facilitate efforts to engineer particular biochemical pathways. Certain traits, such as the expression of proteins that control insects or genes conferring herbicide tolerance, are good candidates for plastid-based expression. Other genes that require precise tissue specific or temporal expression are probably not suited for insertion into the chloroplast since specific promoters and control elements that can confer controlled expression are not available.

Dufourmantel *et al.* (2004) reported the first demonstration of plastid transformation in soybean. These researchers delivered a gene that detoxifies spectinomycin into embryogenic cultures by particle bombardment. The transformation cassette was similar to that used for tobacco transformation, employing a strong plastid promoter (Prn) from the 16S ribosomal RNA gene from tobacco chloroplast (Maliga, 2004). Two days after bombardment, the embryogenic tissue was placed on solid medium containing spectinomycin and subsequently subcultured about every 2 weeks to fresh medium. Transgenic events appeared as green, embryogenic calli from the bleached, spectinomycin-sensitive tissue. About one transgenic event was recovered from every two plates of bombarded tissue. The selection scheme produced tissue that was fully “transplastomic” meaning that all copies of the plastid genome harbored the transgene. This group went on to demonstrate that the plastid genome stably maintained the transgene for at least six generations and that application of spectinomycin was not necessary for stable inheritance (Dufourmantel *et al.*, 2006). They also showed that *Bt* genes can be incorporated into the plastid genome of soybean, leading to high level expression (Dufourmantel *et al.*, 2005). Expression of *Bt* genes in crops by the nuclear machinery requires synthetic and codon modification to improve translation, protect the mRNA from degradation, and prevent early translation termination. In contrast, the native *Bt* genes can be expressed in plastids from bacterial coding segments. High copy numbers of plastid genomes (up to 10000 per single cell) with highly active inter- and intramolecular exchange would allow for the propagation of the transgene throughout the plastid genome pool very quickly (Goulding *et al.*, 1996), and result in high transgene expression. Field-level tolerance to glyphosate was obtained by expression of prokaryotic *EPSPS* genes in tobacco plastids; the protein levels were as high as 5% of total soluble protein, which is much higher than the expression level from transgenes in the nucleus (Ye *et al.*, 2001). Recently, Dufourmantel *et al.* (2007) introduced a bacterial gene coding for 4-hydroxyphenylpyruvate dioxygenase (HPPD) into the plastid genome of soybean. This enzyme catalyzes a step in the pathway leading to

plastoquinone and vitamin E and herbicides such as sulcotrione and isoxaflutole (IFT). Expression of HPPD from the plastid genome led to high levels of expression (5% of total soluble protein) and tolerance to IFT. Nuclear transformants carrying a chloroplast targeted *HPPD* gene under control of the strong *rbcS* promoter displayed herbicide damage after treatment with IFT, while the chloroplast transformants did not show damage.

Finally, a majority of cultivated crop plants inherit their plastid genomes uniparentally through a strict maternal inheritance (Maliga, 2004). Transferring transgenes in plastids under the control of plastid promoters can reduce or eliminate the transgenic pollen drift that could cause gene flow.

Expression of transgenes in the plastid genome for containment and high-level expression of recombinant proteins for pharmaceutical and industrial applications are desirable. Soybean represents a promising target for plastid transformation. The nature of the tissue used for gene transfer into the nuclear genome provides an ideal target for chloroplast transformation. DNA is typically delivered to this target by microprojectile bombardment using the gene gun, which is the preferred means. However, plastid transformation is routine only in tobacco, the soybean plastid transformation remains a challenge.

3.3.6 Marker-free products

Selectable marker genes based on antibiotic or herbicide resistance are widely used for identification of transformed tissues and plants. However, marker genes may be undesirable in the final products due to their potential horizontal transfer and other unexpected effects (Rommens, 2006). The presence of resistance genes against antibiotics in food products might theoretically lead to the spread of these resistances via intestinal bacteria in human populations, although there is no evidence supporting this proposition (Puchta, 2003).

There are several strategies to generate marker-free transgenic plants. (1) Without using marker genes, the isopentenyl transferase gene from the T-DNA of *Agrobacterium* was successfully used for the selection of transformants (Ebinuma *et al.*, 1997). Positive selection can be used to identify

the transformants by PCR assay or enzymatic assay if the transgene encodes an enzyme. (2) Eliminate marker genes by co-transformation, the desired gene and the marker gene can be supplied on two T-DNAs within the same binary vector (Komari *et al.*, 1996; Lu *et al.*, 2001) or on two binary vectors within the same *Agrobacterium* (Daley *et al.*, 1998) or with two different *Agrobacterium* strains (Komari *et al.*, 1996). However, the limitation of this strategy is that nonlinked transgene loci have to be separated by crossing, which is time consuming. (3) Excise the marker gene using site-specific recombination, a kanamycin gene placed between two *lox* sites was excised from the tobacco genome by the expression of Cre recombinase (Dale and Ow, 1991). This could be applied with other two site-specific recombination systems: FLP/frt (Luo *et al.*, 2000) and R-Rs (Sugita *et al.*, 2000). The recombinases, Cre, Flp and R, are not host-specific factors and can function in plants. A chemical-inducible site-specific DNA excision system has been developed in *Arabidopsis*. In the system, Cre expression was tightly controlled by the estradiol inducible XVE transactivator (Ow, 2001, 2002; Zuo *et al.*, 2001). Srivastava and Ow (2004) proposed the use of two site-specific recombination systems—one for integrating the DNA and the second for removing DNA sequences that are not needed after DNA transfer.

Transgenic plants without marker genes could win regulatory approval and public acceptance with less concern of food safety and environmental impact. The future transgenic soybean plants should adopt the marker-free technology in order to eliminate undesired sequences from the final commercial products.

3.3.7 Site-specific integration

Site-specific integration technology would help place gene(s) or trait(s) at a known and characterized site(s) in elite genotypes to yield predictable function as a hybrid product. Such targeted gene expression may also be necessary to satisfy regulations regarding food safety, such as potential allergenicity effects resulting in increased health risk to consumers.

Site-specific integration using flippase recombinase (FLP)/FLP recombinase target (FRT)

from yeast (Sadowski, 1995) and Cre/lox system (Sauer and Henderson, 1988; Ow, 2002) required two types of transgenic events—a target event (permanent insertion site, i.e., FLP recombinase that stimulates chromosomal recombination and binds to FRT sites) and a donor event (transgene donor of gene of interest). FRT sites will present in both target and donor events for exchange or excision of DNA sequences between FRT sites within two events via pollination. Target sites are fully characterized for characteristics like copy number, flanking sequence, chromosome location, and position before trait insertion.

This strategy will significantly reduce transgenic event production efforts compared to random insertion of transgenes. Furthermore, this technology could help to advance molecular gene stacking for multiple traits.

3.3.8 Transgene-stacking technology

The next generation of transgenic soybean products will have stacked traits, such as stacking two *Bt* genes or herbicide resistance genes for more effective insect or weed management. Therefore, it is very important to develop efficient gene-stacking technology. Transgene stacking can be achieved by sexual crossing, co-transformation, or retransformation as described by Eckert *et al.* (2006).

Crossing two transgenic lines with different transgenes can be easily achieved by conventional breeding with MAS technology. Co-transformation of two or more transgene constructs is possible using particle bombardment (Eckert *et al.*, 2006; Kinney, 2006). One or more transgenes can be expressed in a same expression cassette. Retransformation of a transgenic line with a new construct can be carried out with the same method as the initial transformation. However, this method faces other challenges. Retransformation requires new or different selection markers, and the frequency of events that exhibit proper expression for all of the transgenes is low. Site-specific integration technology takes an important role in developing an optimized gene-stacking method.

Kinney (2006) successfully co-expressed five genes and established a novel fatty acid synthetic pathway in transgenic soybeans. These results

demonstrate that gene-stacking technology has advanced and it is possible to develop transgenic soybeans with multiple improved traits. Transgenes can also be stacked with native genes by conventional breeding. Narayanan *et al.* (2004) successfully developed broad-spectrum bacterial blight resistance in rice by combining MAS technology and transgenic engineering. They transformed the *Xa21* transgene into rice and combined this transgene with other R genes by MAS technology. This is an example of how conventional breeding and the transgenic approach can synergistically advance product development.

3.4 Intellectual Property Rights, Industrial Perspectives, Biotechnology Acceptance, and Economic Consequences

Plant biotechnology holds a great deal of promise to enhance our lives and protect our planet. With the world population expected to reach nearly nine billion by 2050, biotechnology offers new potential for sustainable living, healthy eating, and battling diseases while reducing our footprint on the planet.

The broad field of biotechnology presents important opportunities that should be explored and developed to identify those safe and commercially viable applications that bring significant benefits to the society. These opportunities arise in areas including food, materials, energy generation, polymers, sensors, and electronics. Benefits may include lower cost, higher quality products and reduced reliance on fossil fuels, along with other environmental benefits.

3.4.1 Intellectual property rights (IPR) in agricultural biotechnology

At present, the majority of plant biotech investments occur in developed countries, and about 70% of that investment is from the private sector. Several developing countries currently have access to transgenic products that are spillover from developed countries, particularly from the United States (Acquaye and Traxler, 2005). As the pace of scientific discovery in agricultural biotechnology has accelerated over the past few decades, the use of

patents and other IPR to protect these discoveries has increased tremendously.

IPR refer to inventors' exclusive rights provided by various laws including patent law, copyright law, trademark law, trade secret law, industrial design law, and potentially others. These rights allow their owners to exclude competitors from "making, using, offering for sale, or selling" an invention for a limited period of time. The plant variety protection (PVP) for plants was first available in 1970, but for hybrids beginning only in 1994. Conversely, patent protection for plants first became available in 1985, and firms used both patents and PVP system for some years. Although cost of utility patents is higher, PVP allows farmers' reuse of seed (although not an issue for F₁ hybrids) as well as open breeding access. In recent years patents have clearly become the form of choice. Pioneer Hi-Bred Inc., A DuPont Company holds more patents and PVP certificates than any other company (Lesser, 2005).

The investment in an innovation, such as herbicide tolerance through plant biotechnology, is often large including higher regulatory costs. However, an incentive for private-sector innovation in plant biotechnology for crop improvement is that the return of the investment is expected to be higher since the marginal cost of producing additional improved seed is very small (Acquaye and Traxler, 2005). The IPR has provided innovating firms with some monopoly power to set a price higher than marginal cost in the seed market (Falck-Zepeda *et al.*, 2000).

The high transaction cost of tracking down and licensing the multiple patents required to be able to commercialize the products is a concern. For example, DeKalb's patent claiming transgenic Basta-resistant corn delayed Holden's launch of Basta-resistant corn for at least a year (Pray and Naseem, 2005). Excessive patenting upstream could result in increased transaction costs for downstream innovators, slowing research activities. The patent holders could extract licensing fees or royalty payments from downstream innovators. Therefore, it will increase costs for downstream innovators to divert scarce research resources from product development to "reinventing the wheel" in order to get around existing roadblocks (Pray and Naseem, 2005). After the first regulatory release for planting a genetically engineered crop was granted in 1983, plant biotechnology research

increased very rapidly in the late 1980s and 1990s in response to the technological opportunities offered by the breakthroughs of cellular, molecular, and genomic biology, and stronger IP rights. A relatively small number of firms own key IPRs for the development of agricultural products through plant biotechnology.

To avoid higher costs of licensing and royalty payments and to facilitate successful commercialization of new complex biotechnology products, industry responded with aggressive unprecedented consolidations of the agricultural plant biotechnology and seed industries in the late 1990s so that enabling intellectual properties were owned by the same company. After the industrial consolidation, just six big firms—US firms Dow, DuPont, and Monsanto and European firms BASF, Bayer, and Syngenta, controlled over 40% of the private-sector agricultural biotechnology patents issued in the United States through 2000. DuPont and Monsanto hold the largest corporate portfolios, with 13% and 14% of the industry's count of US patents, respectively, followed by Syngenta with 7%, Bayer with 4%, and Dow with 3% (Graff *et al.*, 2003). The six big firms also account for over 80% of transgenic crop field trials for regulatory release in the United States. It is a clear indication that the research being done has become quite concentrated. Subsidiary firms contributed 70% of the patent stocks of the "Big Six", although parent firms contributed better patents by one measure of patent quality (King and Schimmelpfennig, 2005).

There are some concerns of IPRs owned largely by few private firms. Farmers are concerned that the monopoly power of agricultural biotechnologies may set a higher premium price for the improved seeds. Meanwhile, too many patents and too much concentration in the Big Six may slow down research for new biotechnology development. The IPRs could raise the bar for new entry of agrobiotech business. Japanese companies have been forced out of this arena because of difficulties reaching a reasonable deal for the key promoters, markers, and transformation technology with Monsanto and others (Pray and Naseem, 2005).

The IPRs in plant transformation, as an example, illustrated the relationship between the public and private sectors and the history and impact of the IPRs on plant biotechnology.

Most plant transformation technology, including soybean transformation, came out of research conducted at public-sector labs. The major private biotech firms also contributed to the development of these techniques and now own (or have exclusive licenses to) all of the major technologies (Pray and Naseem, 2005). Monsanto, the Max Planck Institute, University of Leiden (owned by Mogen/Zeneca now Syngenta) and The Washington University group applied for patents on *Agrobacterium*-mediated transformation methods in 1983, but they were not issued until almost 17 years after the application due to interference proceedings in the United States. The Max Planck Institute in Europe eventually won the patent. Japan Tobacco holds the patent on using *Agrobacterium* to transform monocots, Cornell holds the patent on the Helium Biorad particle that was exclusively licensed to DuPont, and the patent for the electric discharge particle gun is held by Agracetus (now owned by Monsanto).

Lawsuits can easily cost millions of dollars to litigate. In 2002, Syngenta claimed that Monsanto and Delta and Pineland infringed their patents on *Agrobacterium* transformation of dicots such as cotton and soybeans, and required them to pay royalties on their *Bt* and herbicide dicot crops or to stop selling them (Syngenta, 2002). Monsanto then launched countersuits, leading this to become a long, expensive battle that was not settled for several years. The difficulty of getting access to the whole package of plant transformation technology appears to have kept some firms from entering the plant biotechnology business. On the other side, the net impacts of patents have stimulated research on these tools that has led to major increases in their technical efficiency. The cost of plant transformation has also dropped dramatically—although possibly much more for the patent holders than the licensees (Pray and Naseem, 2005).

Internationally, the public sector has generated 24% of the IP in agricultural biotechnology. The largest public-sector patent holders are the University of California and the USDA, with 1.7 and 1.2%, respectively (Graff *et al.*, 2003). Public-sector technology transfer has several major goals: bringing the benefits of public research and development to potential users, finding innovative ways to fulfill agency missions in an era of relatively scarce resources, influencing the direction of

technology development, and enhancing research funds through licensing revenues (Rubenstein and Heisey, 2005).

Public funding for research emphasizes the discovery of a wide spectrum of previously unknown gene functions and private research focuses on application-driven research in a more narrow range of established product lines (Graff *et al.*, 2003). We shall see the continued trend of cooperation between public and private sectors in working toward the development of IPR.

3.4.2 Industrial perspectives

Transgenic product development through plant biotechnology research is not a single activity but a sequence of activities that covers the continuum from product concept, gene discovery, transformation, greenhouse and field evaluation, transgenic event and line selection, breeding into commercial varieties with transgenic trait, field production, marketing, and post marketing to regulatory approvals and biotechnology acceptance. The process of producing a transgenic variety uses public knowledge, proprietary knowledge, technology protected by intellectual property, money, and other inputs. Scientists in a research program start with basic knowledge about plants, pests, the environment, and market needs. To develop transgenic plants, they insert promising genes and promoters into available plant lines using plant transformation technology. Once the plants have been transformed, they are first tested in greenhouses. The varieties that survive this round of testing are then tested in fields. Before firms or research institutes can conduct field trials, they must obtain permission from USDA-APHIS. Under the authority of the Federal Plant Pest Act, APHIS regulations provide procedures for obtaining a permit or providing notification prior to introducing a regulated article 1 in the United States. Firms or research institutes that are conducting research to develop genetically modified organisms (GMOs) must apply to APHIS for a permit or notification 2 to conduct field tests (also known as a “release into the environment” permit).

To obtain legal approval to use a new transgene in commercialization, the firm must apply to the USDA for deregulated status. If the USDA

grants the application, the new plant is no longer a regulated article and can be treated as a nontransgenic plant for commercialization purposes. Meanwhile, the scientific community will continue to weigh the risks and benefits of plant biotechnologies, realizing that there may never be enough evidence to ensure zero risk. Only data will reveal tolerable levels of environmental risks on a case-by-case basis (Gewin, 2003).

Herbicide resistant soybean developed through plant biotechnology demonstrates the benefits that can be obtained in soybean production. More emerging plant technologies will be applied to further improvement of soybean to meet needs in the food, feed, industrial use, and energy businesses. Despite all the opportunities, transgenic soybeans face numerous challenges. Every transgenic product is subject to extensive regulatory scrutiny and will face many requirements of field research and data for biosafety assessment. From gene discovery to the launch of a transgenic product, regulatory approvals can reach \$44–88 million US dollars over 8–10 years (Monsanto data; Dill, 2005). Given the commitment necessary to commercialize these products, timely technology introductions are the keys to acceptance by the commodity industry and public. Sometimes, it is difficult for developers to earn sufficient returns on research investment for many biotech traits that could be beneficial for producers, processors, and consumers.

At least six commercial milestones have been identified that should be met before launching a product. The milestones include: (1) regulatory approvals in the United States, Canada, and Japan, (2) approvals or marketing arrangements in place in major export markets, (3) grain handling, sampling, and detection methods implemented, (4) comprehensive stewardship programs in place, (5) quality varieties that meet end user need, and (6) buyers identified (Dill, 2005).

To accelerate the development of transgenic products, Bradford *et al.* (2005) proposed that the regulatory emphasis should focus on the phenotype of the transgenic products as the conventional breeding products. This can save a lot of efforts in characterizing the transgene in the transgenic crops. They suggested elimination of event-specific regulation. With a deeper understanding of the transgenic products, the expensive and time-consuming regulatory process

may be simplified while still acquiring the key risk assessments.

3.4.3 The challenge of global biotechnology acceptance

Although more than one billion acres of transgenic crops, including glyphosate-resistant soybeans, have been planted globally since 1996 (James, 2006), global biotechnology acceptance is a challenge. To improve the regulatory system for food and environmental safety, the questions relating to environmental monitoring, traceability, and labeling for risk assessment can be addressed. Since 1998, the European Union has imposed a moratorium (9433/1/99, 90/220/EEC) on new approvals for the release of GMOs. The risk assessments include evaluations of both direct and indirect, as well as short- and long-term effects, plus the uncertainty at various levels (2001/18/EC; Tencalla, 2006). One in two Europeans, polled in the latest Eurobarometer survey published in June 2006, believes biotechnology will improve quality of life. Most Europeans are in favor of medical (red) and industrial (white) biotechnology, but they are still mostly skeptical about agricultural (green) biotechnologies (Gaskell *et al.*, 2006).

Regulations covering the traceability and labeling of GMOs and the traceability of food and feed products produced from GMOs came into force in April 2004 in the EU. According to these, foods produced from biotechnology products must be labeled. The threshold for labeling measurable incorporation of GM material is 0.9% in any ingredient in the food product (Madsen and Sandoe, 2005). Since 2003, new rules and guidelines are in place to address these risk assessment questions, but the system is still moving forward very slowly. The United States, Canada, and Argentina launched an official complaint to the World Trade Organization (WTO) against the EU regarding the technical barrier for the agricultural commodity in May 2003. Such unresolved issues caused a deeper economic analysis of some trade-related consequences of GM crop adoption (Sobolevsky *et al.*, 2005).

An identity preservation system for agricultural commodity could be used to ensure that GM

and non-GM products are segregated along the production, marketing, processing, and distribution chain in countries requiring product stream segregation. However, US farmers growing conventional soybeans could spend \$19.8 per metric tons, or 11% of the price received (Sobolevsky *et al.*, 2005), if required to segregate GM products. When growing transgenic crops that require identity preservation, the high cost of segregation may negate most of the welfare gain and make the earnings almost equal (Sobolevsky *et al.*, 2005). For international trade, the soybean imports alone in China could total about 13.98 million US dollars in 2005, and for some regions in Brazil, the costs could be close to 9% of a shipments product value (www.agritrade.org).

In addition to the political and trade impacts on the global acceptance of plant biotechnology, public concern is also an important factor for biotechnology acceptance. The public seems to have an agenda that goes beyond risks to human health and the environment. A major concern here is that GM crops, including herbicide- and insect-resistance traits, are primarily useful to the farmer and only indirectly useful to citizens. Concerns about socio-economic effects (industrial patents, monopolization, and globalization) and moral issues (sustainable agriculture through organic farming, freedom of customer choice, and unnaturalness of biotechnology derived products) seem to add to the opposition (Madsen and Sandoe, 2005; Gaskell *et al.*, 2006).

Public perception about risks can be explained by the social psychology model (Slovic, 1987). Three factors are the primary determinants of perceived risks: dread risk (defined as lack of control, dread, catastrophic, fatal consequences), unknown risks (defined as hazards judged to be undetectable, unknown, delayed harmful consequences), and the number of people exposed to the risks. The risks from RRTM crops are associated with two technologies—DNA technology and pesticides. According to the above model of social psychology, both of these technologies are viewed as high on the risk scale from a lay point of view. Customers cannot control the technology because biotech products are visually undetectable. Many people are concerned that GMOs could have unknown irreversible long-term effects on humans and biodiversity, however, there is no evidence supporting the fears thus far.

Trust is created rather slowly, but may be destroyed in an instant, and negative events are far more likely to have a powerful effect on trust than positive events. Distrust tends to perpetuate distrust (Madsen and Sandoe, 2005). The first introduction of Flavr Savr delayed-ripening GM tomato in United Kingdom in 1996 was largely successful. However, a multiple wave of food scandals (Mad Cow Disease, *E. coli* 157, etc.) generated a context of distrust toward policy makers, industry, and scientists. This unease may translate into the generalized “zero risk” approach toward new innovations, which is experienced today in some EU countries with regard the plant biotechnology (Tencalla, 2006).

The potential for rejection of products derived from biotechnology in the EU and other countries has caused growers, millers, grain processors, and others to hesitate in the adoption of plant biotechnology. However, no scientific advisory panel in any country has confirmed any concern as to the safety of biotechnology-derived products that have been evaluated (Dill, 2005). It is unfortunate that political, trade, and economic issues rather than scientific data can negatively influence plant biotechnology acceptance in the EU and the rest of the world.

Developing countries accounted for 40% of the global biotech crop area in 2006, equivalent to 40.9 million hectares (James, 2007). However, the common challenges in the developing countries are establishing biosafety laws and regulations, building capacity to evaluate and approve the release and import of transgenic products, and managing the IPR. In developing countries, the public sector's scientific contributions occurred far upstream, or were missing altogether. Paraguay is a striking example. In 2005, it had the sixth largest GMO area in the world, yet it has no biotechnology research capacity. It seems likely that while in the short term technology can be accessed without these capacities, future use of GMOs will be limited (Traxler, 2006).

Two international fora are also involved in biosafety, the Cartagena Protocol on Biosafety (BSP) (<http://www.biodiv.org/biosafety/default.aspx>) and Codex Alimentarius (<http://www.codexalimentarius.net/web/index.en.jsp>). Codex, which establishes international quality and food safety standards, is currently having discussions on transgenic traceability and labeling. The

BSP, which establishes requirements for the movement of “living modified organisms” (LMOs) between countries, is in the process of setting forth documentation requirements for commodity shipments of LMOs for food and feed purposes. The United States is not a party of the BSP. Requirements relating to documentation of the presence of LMOs in shipments of products in international trade provide an additional cost and challenge for US exporters.

The scientific and technical success of biotechnology products is the first step toward commercialization and benefits to all human beings. More work toward a broader approach, taking into account the politics, economics, society, and international trade issues, is needed for the acceptance of plant biotechnology as a cutting-edge innovation for plant improvement. Some of these factors are nonscientific in nature, and cannot be addressed from a scientific/technical perspective alone (Madsen and Sandoe, 2005).

There are many stakeholders of plant biotechnology products. Engagement of all the stakeholders in addressing the value judgments, uncertainties, and limitations involved in the risk assessment is likely to be the best way of avoiding public distrust (Madsen and Sandoe, 2005). Public education on scientific risk assessment must be presented in a way that is easy to understand. Industrial stakeholders will need to work together with biotechnology stakeholders to help the general public understand the impact of additional regulatory proposals and the safety procedures and national regulatory systems that are already in place.

Industry in plant biotechnology must take scientific, societal, ethical, environmental, and cultural impacts into consideration when designing and commercializing products. In 1999, DuPont formed an independent and prestigious panel of individuals from around the world “to guide our actions, help us create positions on important issues, and guide and challenge us in the development, testing, and commercialization of new products based on biotechnology.” The Bioethics Guiding Principles were established in 2003 to show their commitment to a comprehensive stewardship approach to biotechnology and the use of this science to help build a sustainable future (http://www2.dupont.com/Biotechnology/en_US). The use of biotechnology

still has room to grow in developing countries, particularly Africa, and building the capacity for the market in these countries is largely dependent on major players in the industry.

The latest European survey on biotechnology showed that 52% of the 25 000 people polled believed biotechnology will improve their quality of life, which indicates that the optimism about biotechnology has increased since 1999 after a period of decline. The survey also shows a growing level of trust in university and industry scientists at 73% and 64%, respectively (Gaskell *et al.*, 2006). With improved biotechnology products for the consumer’s benefits, a trusted regulatory system, solid science-based benefits and risk assessment, and a responsible product stewardship from premarket to postmarket, the benefits of plant biotechnology will reach more people in the world in the future.

3.4.4 Economic impacts of transgenic soybean

The annual economic value of soybean production in the United States is in the range of 12.6–18 billion US dollars during 2001–2005 (Table 4) (www.nass.usda.gov). Yield is vitally important for soybean producers. Soybean prices have trended downward since 1980. Although prices have been declining, per-acre income from soybeans has increased due to yield improvements and farmer programs that have helped increase net farm income (Soper *et al.*, 2003).

Although soybean yields and production in the United States have increased steadily, the United States share of world soybean production has been

Table 4 US soybean production and economic value (USDA-NASS)^(a)

	2005	2004	2003	2002
Acreage (Million acres)	72.1	75.2	73.4	74.0
Yield (Bushels/acre)	43.3	42.2	39.0	38.0
Price (US \$/bushel)	5.5	5.7	7.3	5.5
Value (Billion US \$)	16.9	17.9	18.0	15.3

^(a) Source: USDA-NASS

declining. In 1991, US soybean production was approximately 2 billion bushels, which was 50% of the world's production. In 2002, production climbed to nearly 3 billion bushels but only accounted for 43% of the world's production. Brazil has massive growth potential in agriculture due to the availability of virgin lands in its vast interior. Under the right economic circumstances, much more of that land could be converted for soybean production. Brazilian soybean producers have proven to be remarkably competitive in terms of relative production costs, and Brazil's average soybean yield has exceeded the United States average in some years (Ash *et al.*, 2006).

Global soybean trade is predicted to rise nearly 4% annually to 97 million metric tons in 2013–2014, compared to 70 million metric tons in 2004–2005 (www.ers.usda.gov). China is the world's largest importer of soybean, with the current United States share of that market at 40%. Increased world soybean production will come mainly from Brazil, because of its available land for cultivation. Ash *et al.* (2006) showed that soybean exports from South America have exceeded US exports since 2002/03, including 2004/05 despite a record US harvest and export volume. Brazil and Argentina have each surpassed the United States in soybean meal and soybean oil exports. However, once Brazil's planting areas are completely opened; there will remain little arable land to develop for global soybean production. Therefore, higher yields will be needed to feed a growing world population. The movement to an enriched diet globally, in the developing world in particular, is putting more pressure on the soybean meal market.

Glyphosate-resistant RR soybeans became available to US growers in 1996, and within 10 years, 89% and 98% of the soybeans grown in the United States and Argentina, respectively, were RR varieties. The economic benefits of the diffusion of transgenic soybean have been widely shared among farmers, industry, and consumers even though delivery has been through the private sector. Transgenic soybean has had a favorable environmental impact by facilitating reduced pesticide use and the adoption of conservation tillage (Traxler, 2006).

Yields of RR soybeans are not significantly different from yields of conventional soybeans in either the United States or Argentina. The

farm level benefits of RR soybeans are generated primarily through reduced herbicide, tillage, and management costs. Many farmers switched to low-till or even no-till cultivation practices after the adoption of RR soybeans. Machinery and labor costs are also lower due to the reduced time needed for harvesting (Qaim and Traxler, 2005). Analysis shows that there have been substantial net economic benefits at the farm level amounting to a cumulative total of \$27 billion (Brookes and Barfoot, 2005).

Farmers, seed firms, and consumers in Argentina and the United States had significant welfare gains that increased as RR soybean adoption increased. In 2001, RR soybeans created more than 1.2 billion dollars, or 4% of the value of the world soybean crop, in economic benefits at the global level. The largest share of these overall benefits went to soybean consumers, who gained \$652 million (53% of total benefits) due to lower prices. Soybean producers received net benefits of \$158 million (13%), and biotechnology and seed firms received \$421 million (34%) as technology revenue (Traxler, 2004, 2006). In 2004, the \$4.14 billion additional farm income generated by RR soybeans is equivalent to adding 9.5% to the value of the crop in the GM-growing countries, or adding the equivalent of 6.7% to the \$62 billion value of the global soybean crop. These economic benefits should, however, be placed within the context of a significant increase in the level of soybean production in the main GM-adopting countries. Since 1996, the soybean area and production in the leading soybean-producing countries such as the United States, Brazil, and Argentina increased by 56% and 66%, respectively (Brookes and Barfoot, 2005).

Even though all of the transgenic RR soybeans used in Brazil and Argentina are the result of technology spillovers from US private firms, the benefits have been widely distributed among the private firms, farmers, and final consumers. In 2001, farmers in Argentina were receiving a surplus of more than \$300 million compared to the US farmers who received a surplus of \$145 million. Although the RR area in the United States is larger than in Argentina, net producer surplus has been larger in Argentina since 1999 because the share of adopting farmers in Argentina exceeds the share in the United States. In Argentina, total variable cost of production is about 8% ($\$21 \text{ ha}^{-1}$) lower

for RR soybeans than for a conventional crop because of weak intellectual property protection and the widespread use of farm saved and black market seeds. Farmers in developing countries have much to gain when they are given access to suitable foreign technologies (Traxler, 2006). Evidence from China (Pray *et al.*, 2002), Argentina (Qaim and Traxler, 2005), Mexico (Traxler *et al.*, 2003), and Romania (Brookes, 2005) suggests that small farmers have had no more difficulty than larger farmers in adopting the new technologies. This suggests that the monopoly position engendered by intellectual property protection does not automatically lead to excessive industry profits.

RR soybean has clear environmental benefits. According to the international classification of pesticides, glyphosate belongs to toxicity class U, "active ingredients unlikely to present acute hazard in normal use." Adoption of RR soybeans led to an increase in the use of a relatively harmless herbicide and a significant reduction in the use of more hazardous herbicides (Traxler, 2006). Since 1996, the use of pesticides was reduced by 172 million kilograms (a 6% reduction), and the overall environmental footprint from GM crops was reduced by 14%. The volume of herbicide use on GM soybeans decreased by 41 million kilograms since 1996 (a 4% reduction), and the overall environmental footprint decreased by 19% (Brookes and Barfoot, 2005). The introduction of the glyphosate-resistant technology has caused a significant reduction in the price of all major herbicides for soybean. It has been estimated that these price reductions have saved soybean growers between \$216 and \$307 million per year in weed control costs (Gianessi, 2005).

Meanwhile, 53% of US soybean growers reported making fewer tillage passes through their field with an average reduction of 1.8 tillage per hectares. RR soybeans have enabled growers to eliminate \$385 million per year worth of tillage in their fields (Gianessi, 2005). No-till helps to preserve the soil texture and reduces the risk of wind and water erosion, with concomitant positive environmental effects. Overall, the number of machinery hours is reduced by 20%, and fuel savings are almost 10 l ha⁻¹ (Traxler, 2006). The adoption of no-tillage farming systems reduces cultivation fuel usage by 36.6 l ha⁻¹ compared with

traditional conventional tillage and 16.7 l ha⁻¹ compared with the average of chisel plough/disk tillage. In turn, this results in reductions of carbon dioxide emissions of 98.8 kg ha⁻¹ and 45.0 kg ha⁻¹, respectively (Brookes and Barfoot, 2005). Furthermore, the use of no-till and reduced-till farming systems utilize less plowing, increasing the amount of organic carbon stored or sequestered in the soil in the form of crop residue. This carbon sequestration reduces carbon dioxide emissions to the environment. The additional soil carbon resulting from reduced tillage with GM crops accounted for a reduction in 9.4 billion kilograms of carbon dioxide emissions in 2004. This is equivalent to removing nearly 4.7 million cars from the roads for a year (equal to 19% of all registered cars in the United Kingdom) (Brookes and Barfoot, 2005).

The new wave of value-enhanced crops or quality traits using plant biotechnology includes those plant varieties that have one or more modified output characteristic, adding end user value to the commodity. These output traits have the potential to add momentum to the agricultural biotechnology industry and to enhance productivity worldwide. The high oleic soybeans have been introduced commercially in the United States, US biosafety field trial data indicate that product quality traits accounted for 18% of all US trials in 2005 (Traxler, 2006).

As illustrated by the RR and high oleic soybeans, biotechnology and molecular farming have exhibited their great power in advancing the development of novel soybean products. Transgenic crops such as RR soybeans significantly benefit growers and permit more efficient use of renewable resources such as land, water, and soil nutrients. Furthermore, transgenic crops such as high oleic soybeans significantly benefit human life by providing more nutritious foods, desirable feeds, and valuable industrial products. With increased awareness of the benefits and wider distribution of existing and new transgenic soybeans, soybean scientists will further contribute to the public acceptance of plant GMOs. New transgenic soybean products with stacking traits can further benefit human life, environment preservation, and global economic advancement. Once biotechnology has gained widespread acceptance, the miracle soybean will fully express its beauty.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Taxonomically, *Brassica* is a diverse genus within the Cruciferae family containing over 100 species, some of them including several major oilseed species such as *B. napus*, *B. rapa* (syn. *B. campestris*), and *B. juncea*. Other two lesser-known oilseed species are *B. carinata* and *B. nigra*. *B. napus*, also known as rapeseed, is the most widely cultivated oilseed in many parts of the world followed by *B. juncea*, which is known as brown mustard or Indian mustard. *B. rapa* is grown on a very limited area in countries like Canada, Finland, China, and India. The word “rape” in rapeseed comes from the Latin word “rapum” meaning turnip. Turnip, rutabaga, cabbage, cauliflower, brussel sprout, mustard, and many other well-known vegetables are relatives of the three major oilseed Brassicas. The term “rapeseed and mustard” includes these three major oil species (*B. napus*, *B. juncea*, and *B. rapa*).

The cultivated oilseed species *B. juncea*, *B. napus*, and *B. carinata* originated in nature from interspecific crossing between the diploid progenitors followed by chromosome doubling of the interspecific hybrids as hypothesized by U (1935) and shown in Figure 1. The relationship between the diploid species and tetraploid species presented in Figure 1 is also called as the U-Triangle.

Brassica crops are among the oldest cultivated plants known to humans with written records dating back to 1500 BC (Prakash, 1980). Archaeological evidence of their importance dating back to 5000 BC has been reported (Yan, 1990). Ancient Sanskrit writings dating back to 2000 BC describe *B. juncea* and *B. rapa*. *B. napus* is thought to have originated in Europe especially in Mediterranean areas where *B. rapa* and *Brassica oleracea* overlapped (McNaughton, 1976). *B. juncea* originated in the Middle East (Prakash, 1980), where its diploid progenitors overlapped. *B. rapa*, which is diverse and widely populated in many parts of Europe and Asia, is thought to have originated in Europe.

1.2 Botany and Reproductive Systems

Flowers in the Cruciferae family have four bifurcated petals with varying degree of incision and deep yellow to pale yellow or cream color. There are six stamens in the flower. The anthers are lower than the stigma at bud stage, however, prior to flower opening, the filaments elongate and push anthers above or at the same level of stigma. Different degrees of self-pollination and outcrossing occur in different species of *Brassica*. For example, *B. rapa* and *B. oleracea* are largely cross-pollinated species due to self-incompatibility (SI); however, *B. napus* is largely a self-pollinated

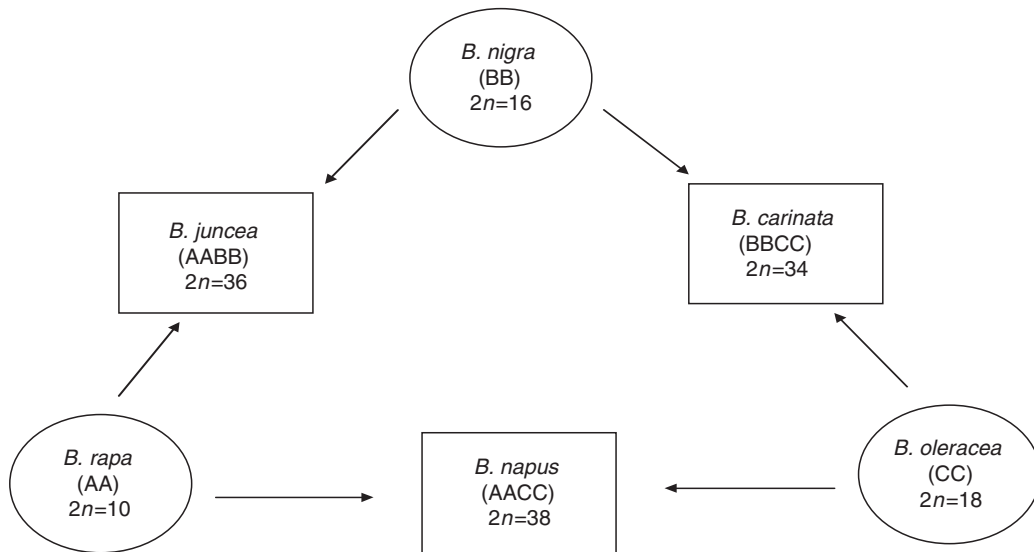

Figure 1 Genetic relationships in different *Brassica* species

species. Due to bright yellow open flowers, insects, especially honey bees can easily be attracted; therefore, there is a varying degree of outcrossing in *B. napus* depending on insect activities and wind. *B. juncea* is also a mostly self-pollinated species similar to *B. napus*. Yellow sarson, which belongs to *B. rapa*, is largely self-pollinated although *B. rapa* as a species is known to be self-incompatible and cross-pollinated.

1.3 Area, Production, Utilization, and Economic Importance

Rapeseed and mustard is the world's third largest oilseed crop after soybean and oil palm. In 2005–2006, the world produced 391 million metric tons of oilseeds, of which rapeseed accounted for 46.4 million metric tons. Total world cultivation of rapeseed and mustard grew steadily by two-and-a-half-fold from about 10 million ha in 1980 to slightly more than 25 million ha in 2005 (Figure 2a). However, in the same time period production increased almost fourfold from 10 million tons to 47 million tons. This increase in productivity has been the result of adoption of improved production technologies and adoption of improved, high yielding, disease and pest resistant varieties. The world's major rapeseed,

mustard, and canola producing countries in 2005 are listed in Table 1.

1.3.1 Transition from rapeseed to canola

Canada played a key role in transition from rapeseed to canola. Canola was an unknown term to many people around the world prior to the 1980s. Canola is not a botanical term but rather a generic term, which describes specific oil and meal quality standards for rapeseed. Canola refers to the seed of *Brassica* species (*B. napus*, *B. juncea*, and *B. rapa*) that contains less than 2% erucic acid in oil, and less than 30 $\mu\text{mole g}^{-1}$ of aliphatic glucosinolates in oil-free meal. Canadian plant breeders, Baldur Stephenson of the University of Manitoba, and Keith Downey of Agriculture Canada, played a key role in developing canola, transforming rapeseed to a major oilseed crop through improvements in its oil and meal quality.

Although in some parts of world, rapeseed and mustard oil has been used in human diets for thousands of years, its use in North America and industrialized world was limited until recently. *B. napus* has been grown in parts of Europe for many centuries and its oil was used in lamps as well as for cooking. Rapeseed and mustard oil is still being used extensively for cooking in India

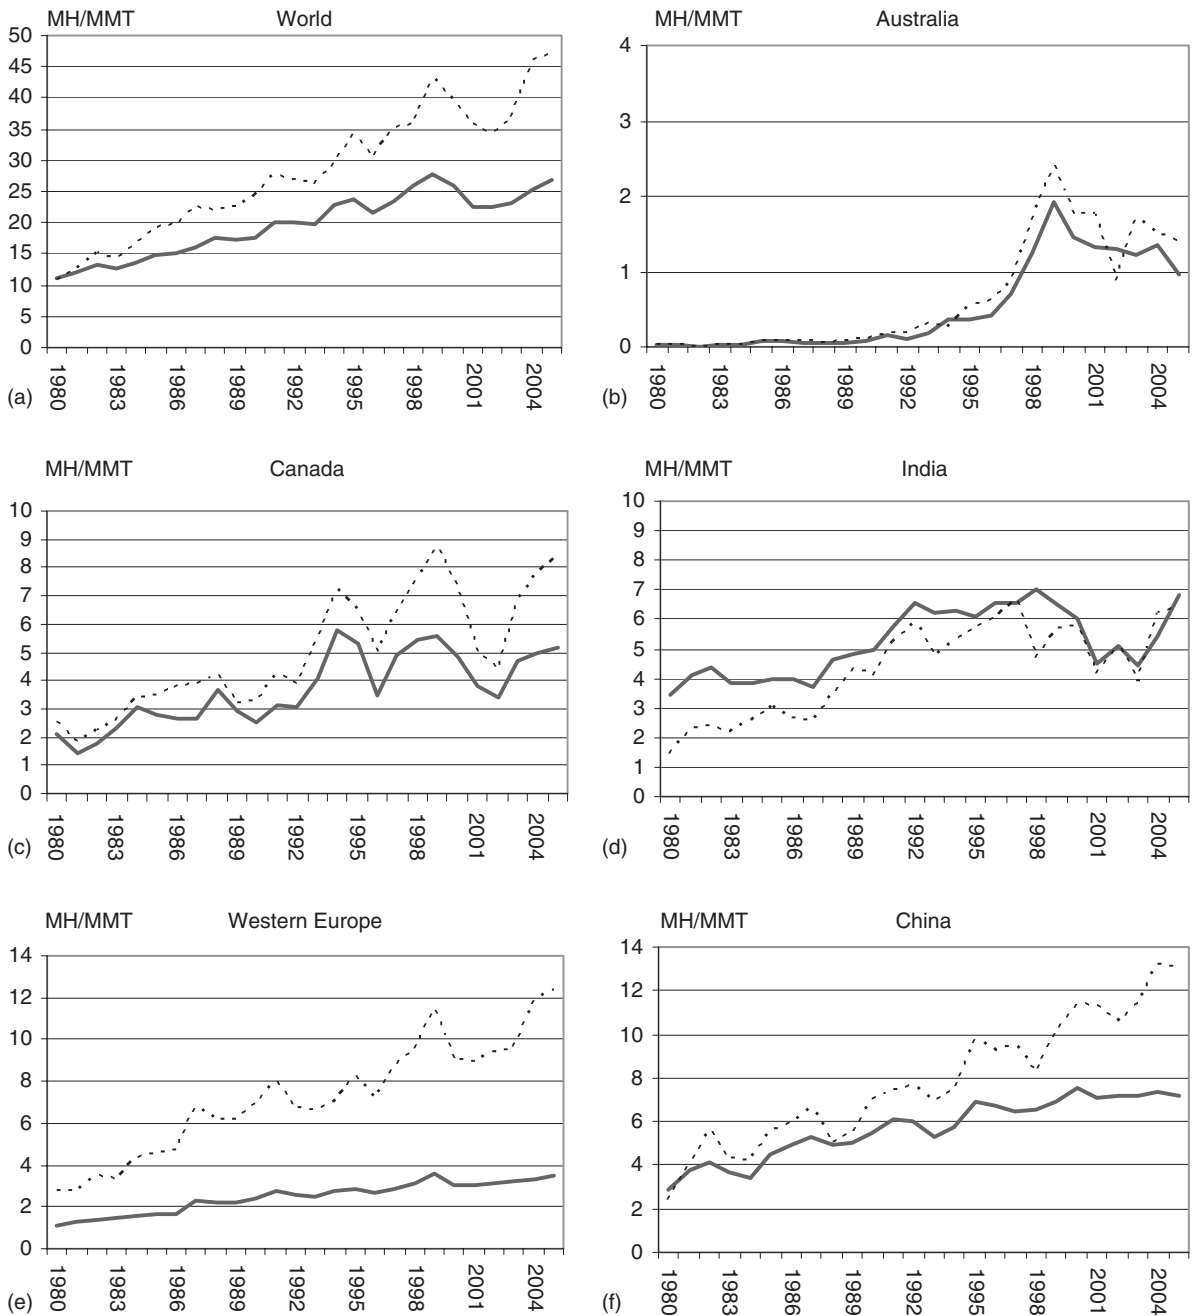

Figure 2 Twenty five years of canola/rapeseed harvested area in millions of hectares (MH) represented by solid line and production of grain in millions of metric tons (MMT) represented by dotted line in (a) World, (b) Australia, (c) Canada, (d) India, (e) Western Europe, and (f) China

and China. When steam powered engines were invented, it was found that rapeseed oil was a better lubricant than other oils, because it would cling to steam washed metal surfaces better than other lubricants. For this reason, its use in marine engines was widespread prior to and during World War II.

During the Second World War, there was an acute shortage of rapeseed oil for the allied navy vessels because most of the supply came from Asian and European sources. The allied navy decided to source rapeseed oil from a safer place—Canada. Prior to the war, rapeseed was grown in Canada experimentally at various research farms. These experiments showed that it could be grown very well in Canada. An immigrant farmer from Poland, who settled in Saskatchewan, introduced *B. campestris* (now known as *B. rapa*) in his garden. He sold it to his neighbors and friends when rapeseed cultivation started to increase in Canada due to war demand. Because of its Polish origin, this species later was known as “Polish” rapeseed. Several tons of seeds of rapeseed (*B. napus*) originating from Argentina was purchased by some US companies and later introduced into Canada. Therefore, *B. napus* was later known as Argentine rapeseed. During World War II, cultivation of rapeseed peaked at about 18 000 ha. After the war, cultivation dropped dramatically to a few hundred hectares. Other oils were in plentiful supply; so there was no demand for rapeseed oil. Since rapeseed was very well suited for Western Canadian conditions, the National Research Council and some oil processors were interested in developing rapeseed oil for edible uses.

Rapeseed oil has a high proportion of eicosenoic and erucic acids in its oil, which are not essential to human growth. Also, erucic acid is poorly digested in human intestine, therefore, nutritionally rapeseed oil had little value as compared to other oils. During the mid-1960s, feeding experiments were conducted with high erucic acid rapeseed (HEAR) oil as a source of fat. In some of these experiments, it was discovered that certain experimental animals developed lesions in their heart tissues after prolonged feeding with high erucic acid feed. Although, the effect of a high erucic diet on human and experimental animals has remained controversial, Canadian plant breeder Baldur Stefansson at the University of Manitoba and Keith Downey at the Agriculture Canada, Saskatoon, started developing low erucic acid rape varieties. The first low erucic acid rapeseed variety Oro was released in 1968 from the University of Manitoba program. During the mid-1960s, rapeseed production increased to about 400 000 ha. In 1967, the Rapeseed Association of Canada was founded.

After oil extraction, leftover rapeseed meal contains protein and sulfur-containing substances called glucosinolates. Glucosinolates, when broken down by an enzyme called myrosinase, produce isothiocyanates, thiocyanates, and toxic nitriles. These substances are toxic to nonruminant animals, and they give bitter taste and reduce palatability to the meal. The rapeseed meal when fed to brown egg-laying hens caused a fishy smell in eggs. Therefore, reduction of total glucosinolates was the only practical solution to these problems. During the late 1960s and early 1970s, breeding efforts to develop low glucosinolate-containing rapeseed were started in Canada. The first low erucic acid and low glucosinolate variety, Tower, was released in 1974. It was demonstrated that the oil and meal produced from this variety was superior to rapeseed oil and meal. Other low erucic acid and low glucosinolate rapeseed varieties followed. During this time, the double low (low erucic acid and low glucosinolates) rapeseed varieties were gaining popularity in Canada. In 1978, the term “Canola” was trademarked by the Western Canadian Oilseed Crushers’ Association (now the Canadian Oilseed Processors Association—COPA) to differentiate the superior low erucic acid and low glucosinolate varieties and their products from the older rapeseed varieties.

During 1979, 3.4 million ha of canola was seeded in Western Canada. People around the world noticed the developments in Canada. Japan started to import large quantities of canola grain for its domestic use. In 1980, the canola trademark was transferred to the Canola Council of Canada. Canola revolution had already begun in Canada.

1.3.2 Canola and rapeseed production in major growing countries

1.3.2.1 Canada

Rapeseed, when introduced in Canada in early forties had less than 18 000 ha of cultivation. During the sixties, after significant breeding efforts toward the development of high-quality canola varieties, area of production increased steadily. Rapeseed became a very important crop in Western Canada. In 1970, Canada cultivated 1.64 million ha of rapeseed, and produced 1.64 million tons of rapeseed averaging about a ton per hectare. In 2005, the cultivation increased to 5.15 million ha, producing 8.45 million tons of canola and averaging about 1.64 t ha⁻¹ (Figure 2c). The average yield has increased during the last 10 years due to the introduction of high-yielding canola varieties resistant to disease and various herbicides.

Canada was the first country in the world to introduce herbicide tolerant *B. napus* varieties in mid-1980s. Herbicide tolerant canola makes weed management easy. Herbicide tolerant canola can be sprayed with the herbicide for which the tolerance is carried by the variety. All other weeds will be killed while plants of the herbicide tolerant (HT) variety will survive. A wild *B. campestris* mutant tolerant to atrazine herbicide was found in natural weed population (Beversdorf *et al.*, 1980). It was later discovered that this trait was inherited through cytoplasm and was introduced in commercial canola cultivars. The first atrazine tolerant canola variety OAC Triton was released in 1984. Because of negative impact of this cytoplasmic mutation on yield, vigor, and oil content, Triazine tolerant canola varieties were grown on limited acres before the development of other modes of herbicide tolerance. Later, three modes of herbicide tolerant canola (*B. napus*)

varieties: Glyphosate tolerant—called Roundup resistant, Glufosinate tolerant—called Liberty resistant, and Imidazolonone tolerant also known as Pursut Smart, Odyssey Smart, and later known as Clearfield canola were registered in 1995. Originally, sources for the first two modes of herbicide tolerance (Glyphosate and Glufosinate) were developed through genetic engineering while the third one (Imidazolonone) was developed through microspore mutagenesis. First time in 1996, the herbicide tolerant varieties were grown on limited acres in Western Canada, but within a short period of time, the herbicide tolerant canola varieties were widely adopted by Canadian farmers. By 2005, more than 90% of Canadian canola crop was seeded with one of the three types of the herbicide tolerant canola.

Up until 1995, Canadian canola included two species, *B. napus* and *B. rapa*, with roughly 70:30 ratio. *B. rapa*, being frost tolerant and earlier maturing than *B. napus* has been suitable for cooler areas of prairies, especially in Northern Alberta (Peace River area), Central Alberta in the foothills of Rocky Mountains, and Northern Saskatchewan where frost-free days are limited. Traditionally, *B. napus* has been higher yielding than *B. rapa*. With the introduction of herbicide tolerance technologies and heavy breeding effort in *B. napus*, yield gap between *B. napus* and *B. rapa* widened during the later part of nineties. Also, mid-early maturing high-yielding herbicide tolerant *B. napus* varieties and hybrids became lot more profitable than conventional *B. rapa* varieties, which caused severe drop in *B. rapa* acreages to the point that it is hardly grown in Western Canada.

The Canadian canola varieties, mostly spring type, are planted in late April and early to mid-May and are harvested in fall (late August to early October) depending on location and season. In 1985, canola oil was granted GRAS (Generally Recognized As Safe) status by American Food and Drug Administration. This development paved the way for increased interest in canola oil by the US food manufacturers and oil processors. Also, more and more reports were coming out from around the world about the nutritional value of canola oil. With the increased import of Canadian canola grain and oil, interest in canola cultivation began to increase in the United States where

winter canola varieties were tried in Kentucky, Ohio, Idaho, and Washington states and spring canola varieties were tried in Georgia, Alabama, North Dakota, Minnesota, and Montana. Due to several production related issues and disease and pest problems, canola production in the United States has remained restricted to 0.4–0.6 million ha only in Northern Plains (North Dakota, Minnesota, Montana, etc.)—where many of the Canadian bred spring varieties are suitable for cultivation.

1.3.2.2 Europe

The principal canola growing countries in Western Europe are France, Germany, the United Kingdom, Denmark, Sweden, and Finland. In Europe, the winter form of rapeseed is grown, which is planted in fall and harvested in late spring to early summer the following year. A very small proportion of spring rape is also planted in the United Kingdom, Sweden, Denmark, and Finland. Eastern and central European countries where rapeseed is planted are Poland, Czechia, Slovakia, Hungary, Russia, and Ukraine. Table 2 lists major European countries for 2005 where rapeseed/canola is produced.

The switchover from rapeseed to canola in Western Europe was completed in the mid-

eighties; a decade behind Canada, because of the fact that the breeding cycle in winter rape is much longer than spring canola. Although, the area of cultivation in European countries is less than in Canada, the total production is more than Canada (Figure 2e). Winter type crops generally yield higher than spring type crops and winter canola is no exception to that rule. As shown in Table 1, the average winter canola yield in Western Europe is 3.5 t ha⁻¹ compared to 1.64 t ha⁻¹ in Canada. Herbicide tolerance technology has not been introduced in Europe, mostly due to anti-GM (genetically modified) sentiment and regulatory hurdles.

1.3.2.3 Australia

The spring form of canola is planted in Australia during the fall (mid-April to early May) and harvested anywhere from mid-October (Western Australia) to early December (New South Wales). Canola was not a major oilseed crop until the mid-nineties. During the seventies, Canadian spring canola varieties were introduced in Australia and were not successful because of a virulent form of blackleg (*Leptosphaeria maculans*). Substantial improvement in disease resistance was achieved during the mid-1980s to early nineties and the acreage expanded along with the world canola demand in the nineties (Table 1; Figure 2b). Although, herbicide tolerant canola, mostly triazine and imidazolonone tolerant, have been in cultivation in Australia, the transgenic form of herbicide tolerant canola is not commercialized yet due to state moratoria on transgenic canola crop.

1.3.2.4 China and India

China and India are the two countries in Asia with a huge area planted under rapeseed and mustard. In China, most rapeseed varieties are *B. napus* type and are having semi-winter habit. China has already started to switch from rapeseed to canola type in recent years and has also made tremendous progress in yield and disease improvement. Rapeseed yield per hectare is high in China due to favorable rapeseed growing conditions (Table 1; Figure 2f) and also due to introduction of production technologies and

Table 2 Europe's rapeseed and canola producing countries in 2005^(a)

Country	Area (million ha)	Production (million metric tons)	Yield (Mt ha ⁻¹)

development of high-yielding, disease-resistant varieties.

In India, a huge proportion of acres are planted to spring form of *B. juncea*. Traditionally, a huge area is planted under low rainfall, dry land where moisture stress compounded by disease stress reduces yield. Although, low erucic acid and low glucosinolates (canola quality) traits are available in *B. juncea*, transition to canola quality in Indian *juncea* crop has been very slow. Also, yield has been very low (Table 1; Figure 2d).

1.4 Traditional Breeding and Genetic Improvements

The breeding objectives fall into three major categories: (a) improvement in yield and agronomic traits, (b) improvement in oil and meal quality, and (c) improvement in disease and insect resistance. Overall, these improvements have increased productivity of oilseed *Brassica* crops around the world.

1.4.1 Improvement in yield and agronomic traits

Canola/rapeseed has undergone intense genetic improvements during the last 20 years because of tremendous investments in biotechnological research in public and private organizations as well as commercial plant breeding activities. *B. napus* has been the most amenable species when it comes to tissue culture response, transformation response, embryogenesis, and application of other DNA-based technologies.

Prior to the introduction of hybrid technologies in rapeseed and canola, pedigree selection has been widely used in developing open-pollinated rapeseed and canola cultivars. One of the main reasons why there was tremendous amount of private investments went in canola research from mid-eighties to mid-nineties was due to the fact that there was a possibility of developing commercial hybrids. Published reports indicated that there was tremendous heterosis available in rapeseed. The seeding rate was reasonably low so that farmers could purchase necessary quantity of hybrid seed and seed multiplication ratio was quite favorable for commercial increase

of seed. Also, there were several pollination control systems, which could be fully developed and used to produce commercial quantities of hybrid seed. Major seed companies saw the opportunities of creating value by combining hybrid performance with traits such as herbicide tolerance, disease and insect resistance, etc. During the last 20 years, hybrid production technologies were developed in *B. napus* and *B. juncea* and were applied in commercializing hybrid canola and rapeseed in Canada, Europe, China, Australia, and India.

In Europe, first winter canola commercial hybrid based on MSL system (Male Sterility Lembke) was registered in 1995 (Frauen and Paulmann, 1999). The MSL system is based on spontaneous mutant selected in the NPZ nursery in 1982. The female line based on MSL system produces pollen under certain environmental conditions making it possible to increase female seed for commercial hybrid production. All other *B. napus* lines restore the MSL female. The transfer of recessive male sterility nuclear mutant from one female line to other line is challenging for MSL system. The hybrids using other male sterility system have been commercialized in Europe since then.

In China, cytoplasmic male sterility (CMS) system called *Polima* was discovered (Fu, 1981). Since then, several other pollination control systems have been reported in China. Between 1992 and 2002, Fu's group released five *Polima cms* based oilseed rape hybrids. According to the Ministry of Agriculture of China, two of these (Huaza No. 3 and Huaza No. 4) were among the top 10 most widely cultivated rape varieties in China between 1999 and 2002. Another successful rapeseed hybrid Quinyou No 2 was widely grown in China which used Shann 2A as a male sterile line.

In Canada, two commercial hybrids, each using different pollination control system, *polima cms* and SI, were released in late 1980s and early 1990s. None of these hybrids was able to capture significant acres due to seed production limitations and only marginal performance advantage compared to the open-pollinated varieties. The *Polima* CMS system broke down and female line produced small amount of pollen under high temperature, therefore, seed production was challenging.

Plant Genetic Systems, Inc. developed a novel *B. napus* oilseed rape hybridization system through genetic engineering. The development of the MS1 and RF1 lines was based on recombinant DNA technology by the introduction of bacterial genes into the *B. napus* variety “Drakkar”. Nuclear male sterility of the first parental line results from the localized production of a ribonuclease (*barnase*) in a specific anther cell layer and at a specific stage in anther development. Fertility restoration in the hybrid line was obtained through insertion, in the second parental line of a gene coding for *barstar*, a specific inhibitor of the enzyme *barnase*. A gene conferring tolerance to the herbicide glufosinate ammonium was inserted in both lines, coding for phosphinothricin acetyltransferase, an enzyme that inactivates glufosinate ammonium through acetylation. Bayer Crop Science acquired PGS system through their acquisition of AgriEvo and commercialized high-performing Glufosinate (Liberty) resistant canola hybrids such as InVigor 5020, InVigor 5030, and InVigor 5070. These canola hybrids set new standards of hybrid performance in Canada and gained increased popularity due to their performance advantage.

INRA in France worked on OGU CMS system in canola and licensed to major companies in early nineties. OGU cytoplasm came from *Raphanus* and was discovered by Ogura (1968). Restorer gene for this sterility was transferred from radish to *B. napus* through interspecific crossing and backcrossing followed by translocation of radish chromosome fragment into *B. napus* genome. The resulting restorer line ended up being higher in glucosinolates. Further crosses and testcrosses revealed that the restorer gene was tightly linked to the gene responsible for high glucosinolates, which made it impossible to develop canola

quality commercial hybrids through OGU CMS system. Various groups, including INRA, spent tremendous effort in breaking an apparent linkage between the restorer gene and high glucosinolate content, and ultimately developed restorer lines, which could be used in commercial canola hybrid development. Pioneer Hi-Bred International, Inc. successfully developed low glucosinolate restorer source and commercialized the glyphosate (roundup resistant—RR) hybrid 45H21 in 2002, which was widely grown in Western Canada. Several Roundup resistant hybrids based on the NPZ-Lembke system have also been commercialized in Canada. By 2004, imidazolonone tolerant canola hybrids were also commercialized from Pioneer Hi-Bred and Advanta Seeds. Western Canadian farmers had wide variety of choices of hybrids with different herbicide tolerance. Although on an average yield basis, the first canola hybrids commercialized in the early and mid-1990s did not outperform open-pollinated varieties by a huge margin, the performance advantage of hybrids was enough in high-moisture environments that farmers realized the benefits of hybrid vigor. Farmers in southern Manitoba and parts of Alberta, therefore, started to adopt canola hybrids. After 2001, newer canola hybrids started to show a tremendous performance advantages over open-pollinated varieties. Results of 2006 Prairie wide Canola Variety Trial (PCVT), co-ordinated by Canola Council of Canada to evaluate commercial canola varieties and hybrids over 32 locations in western Canada, clearly demonstrated superiority of hybrids over open-pollinated varieties (Table 3).

Using the INRA-OGU CMS system canola hybrids have also been commercialized recently in Australia. In India, different male sterility systems are reported (Labana *et al.*, 1992) in *B. juncea*.

Table 3 Average yield expressed as % of control—46A65 for three sets of entries in 2006 Prairie wide Canola Variety Trials^(a)

Type of entries	Number of entries	Range of performance yield % of 46A65	Average performance yield % of 46A65
Hybrid	26	102–129	117
Open-pollinated	19	89–108	101
Synthetics	4	108–116	112

^(a)Source: Canola Council of Canada

To date, large-scale commercialization of Indian mustard (*B. juncea*) hybrids has not occurred in India. As hybrid canola breeding evolves, the diversity of male and female pools becomes very important and introgression of genetic variation from materials of different geographic origin becomes necessary to improve hybrid performance (Btruille *et al.*, 1999; Quijada *et al.*, 2004; Udall *et al.*, 2004).

Early maturing rapeseed and canola cultivars are important when the growing season is short due to weather conditions. In Canada, there are areas in Alberta and Saskatchewan, where frost-free days are very limited. Ten years ago, farmers in these areas used to grow short season *B. rapa* varieties, which matured before frost hit the crop. With the widespread *B. napus* cultivation in Canada, short season early maturing *B. napus* varieties are important in these areas. In Australia, especially western Australia and parts of New South Wales and Victoria under low rainfall conditions, early maturing canola is extremely important. Also, in India, early maturing short season varieties are extremely important in low rainfall areas. In central China, early maturing rapeseed is extremely important for crop rotation with rice and rapeseed. The crop must finish pod filling and be ready for harvest before it becomes too dry otherwise yield would be severely affected in late maturing crop. Usually, early maturing varieties are lower yielding. Degenhart and Kondra (1984) concluded that it was possible to develop early maturing high-yielding canola varieties. Earlier maturity has been one of the important objectives of canola breeders and early maturing *B. napus* varieties such as 44A89, Hudson, 44A04, Peace, 43A56, InVigor 5108, etc. in Canada; *B. napus* varieties such as Monty, Karoo, Drum, 44C73, 44C11, etc. in Australia; and *B. juncea* varieties such as GM-1, Agrni in India were commercially released.

Short plant height and good lodging resistance have been other two important objectives for most canola and rapeseed breeding programs and especially in Europe where winter rapeseed plants can grow very tall up to 2 m in height. Farmers routinely apply growth regulators to reduce plant height of winter rape in Europe. A winter rapeseed dwarf mutant gene called *RREIZH* (*Bzh*) was discovered at INRA in France and molecular markers were developed for this mutant (Foisset

et al., 1995; Barret *et al.*, 1998). This mutant has been utilized in development of commercial semi-dwarf hybrids such as Lutin, PR45D01, PR45D03, Belcanto, Saturnin, and Bambin in Europe. In China, another dwarf mutation called *ndf1* was discovered and inheritance of this mutant was worked out (Wang *et al.*, 2004). Although, short plant height is desirable in Western Canada, Australia, and India, plants do not grow as tall as winter rape in Europe; therefore, semi-dwarf hybrids are not urgently required. Shorter plants tend to stand well and do not lodge making swathing and harvesting operation easier. Lodging resistance is highly influenced by environment and requires recording of observations at many locations in order to characterize a variety.

Canola plants (*B. napus*) shatter and lose seeds if the pods are fully ripened and completely dry. To avoid shattering losses, farmers swath canola and mustard crop when crop is physiologically matured and still has some green pods. It is commonly known that *B. napus* is more prone to shattering than *B. juncea* and *B. rapa*. Although, shattering resistance is very important, it is difficult to screen this trait on large scale in breeding nurseries. Kadkol (1985) studied inheritance of shattering resistance in *B. rapa* and *B. napus*. Later, sequence characterized amplified region (SCAR) markers were developed for shatter resistance (Mongkolporn *et al.*, 1999).

In many parts of the world, rapeseed, mustard, and canola are grown in nonirrigated land relying totally on rainfed conditions. Sometimes during the growing periods, moisture and heat stress are encountered causing significant yield losses. Many times in Western Canada, spring canola crop goes through without rain for prolonged period. Canola plants are very vulnerable during flowering and may not recover from stress after the dry spell is finished. The drought stress reduces yield and oil content and can affect other quality traits. Canola breeders have always been indirectly selecting for consistent performance by testing plant material in varying environmental conditions. It is a well-known fact that *B. juncea* is drought and heat tolerant and can be used in transferring drought and heat tolerance to *B. napus*, however, screening for drought tolerance is complex and would require setting up of a special nursery or screening for other traits associated with drought (Niknam and Turner, 1999). *Sinapis alba* is considered a

drought tolerant species as well, which can be used in transferring the trait to canola.

1.4.2 Improvement in oil and meal quality

Canola grain has about 40–45% oil and 20–25% protein on a whole seed basis at 8.5% moisture. Canola breeders have been trying to increase oil and meal protein contents in canola over several decades. Oil content is highly influenced by environment, especially, availability of moisture and temperature during grain filling. In Canada, the harvested canola crop (Canada #1) over the years has seen slow and steady improvements in oil content (Figure 3) in spite of adverse weather conditions during 2002 and 2003. The improvements in oil contents in Canada would have been even greater if there were incentives for farmers to grow high-oil varieties. Canadian farmers are not paid for how much oil their canola crop produces. In Australia and some European countries the farmers are paid premiums above the defined base oil level. With the recent interest in bio-based fuel, canola oil has gained lot of attention from nonfood users. Increasing oil content in canola, therefore, became a very important goal.

Grami *et al.* (1977) observed high heritability for oil content and reported—0.8 correlation

coefficient value between oil and protein contents. Zhao *et al.* (2005) in a doubled haploid (DH) population derived from Chinese \times European winter rape cross, observed eight quantitative trait loci (QTL) with additive effect, and nine pairs of additive \times additive interactions explained 80% of the genetic variation for oil content. Unpublished research indicates that there is mid-parent and high-parent heterosis for high-oil content. Also, hybrids tend to finish and mature well compared to open-pollinated varieties resulting in higher oil than open-pollinated checks. Recently, the high-oil-producing hybrid 46P50, having 2.5% higher oil than the commercial hybrid check 45H21, has been released for commercial cultivation in Canada.

Canola oil possesses several good nutritional properties in addition to having low erucic acid. It is known to have the lowest total saturated fatty acid content (7.0% in total) among all vegetable oils. Clinically, it is proven that increased intake of fatty foods, especially high in total saturated fatty acids, increases the chance of blocked arteries in adult men and older women. Such blockage, medically known as atherosclerosis, can cause heart attack if not checked and treated. Canola oil, with the lowest total saturated fatty acids, is highly recommended by medical professionals to the high-risk patients and also to the general public. Canola oil is high (60–65%) in monounsaturated fatty acids (oleic acid), which is known to reduce

Figure 3 Oil contents (%) in Canadian canola crop (Canada #1) from 1988 to 2006 expressed at 8.5% moisture [Source: Canadian Grant Commission]

serum cholesterol and low-density lipoprotein (LDL) cholesterol level while not affecting high-density lipoprotein (HDL) cholesterol. The LDL cholesterol is known to be positively correlated with increased risk of heart disease. Canola oil has about 20–22% linoleic acid and about 10–12% linolenic acid. Both of these fatty acids are polyunsaturated fatty acids. Linoleic acid is considered an essential fatty acid because the human body can not synthesize it. Therefore, it must be consumed in the diet. Linolenic acid is converted into ω -3 fatty acids, which are also known to reduce the risk of heart diseases and increase the health of the nervous system.

Since canola oil is slightly higher in linolenic acid, reduction of linolenic acid without changing linoleic acid has been one of the objectives to improve oil quality. Low linolenic acid in canola oil makes canola oil stable, improving its frying properties, and also reduces or eliminates hydrogenation while processing canola oil to margarine. The use of chemical mutagens was applied to induce mutants those resulted in lines with low linolenic acid up to 5% (Rakow, 1973). Later these mutants were used in developing a commercial canola variety at the University of Manitoba, which had less than 3% linolenic acid (Scarth *et al.*, 1988). Jourden *et al.* (1996a) concluded that low linolenic acid in Stellar was controlled by two genes with additive effect. In order to facilitate selection of desired genotypes for low linolenic acid, molecular markers have been developed (Jourden *et al.*, 1996b; Barret, 1999). During the process of hydrogenation trans-fatty acids are produced. Recently, trans-fat has gained a lot of negative attention due to its association with cancer and heart disease. Also, new labeling laws in the United States require all food manufacturers to show the total amount of trans-fat and saturated fat on the labels of all packaged foods. Because of these developments, canola oil with low linolenic acid has been in high demand. Currently in Canada, Dow Agro Sciences has commercialized several NexeraTM high oleic and low linolenic acid canola varieties having Imidazolone tolerance. Cargill has commercialized VictoryTM series of low linolenic acid, open-pollinated canola varieties and hybrids with Roundup resistance. Commercial varieties of *B. napus* with low total saturates (<5%) are not yet available commercially.

Canola grain oil and protein are negatively correlated; therefore, increase in one would lead to a decrease in the other. However, recently, canola breeders have been able to increase both oil and protein simultaneously. Since canola is an oilseed crop, crushers derive most value from oil. Therefore, canola meal is a by-product after oil is extracted. Unlike soybean meal, which is high in protein, canola meal has about 38–42% protein and about 33% crude fiber. Therefore, it is sold at only 70–75% of the value of soybean meal. Also, due to its deficiency in some amino acids, such as lysine and methionine, it is blended in rations along with soybean meal. One advantage of canola meal over soybean is the higher level of rumen-bypass protein, which makes canola meal a preferred component in dairy rations.

Glucosinolates are sulfur-containing substances in meal, which reduce the nutritional properties of the meal. For 2005 and 2006, the total glucosinolates (whole seed basis at 8.5% moisture) for the Canadian canola crop has been 9 and 10.1 μ mole g^{-1} , respectively. The long-term average for total glucosinolates in the Canadian canola crop has been 11 μ mole g^{-1} making it an ideal source of meal for farm animals. Glucosinolates are also reasonably low in the European and Australian canola crops. China is making a good progress toward reducing total glucosinolates in the rapeseed crop. There are several types of glucosinolates, each under the control of different gene or set of genes. The genetics and inheritance of glucosinolates is documented in past publications (Kondra and Stefansson, 1970; Magrath *et al.*, 1994; Mithen *et al.*, 1995; Parkin *et al.*, 1994; Toroser *et al.*, 1995; Sodhi *et al.*, 2002). Rakow and Raney (2003) demonstrated that it was possible to develop *B. napus* lines having zero aliphatic glucosinolates and a total glucosinolates of about 1.0 μ mole g^{-1} . This would further increase the feed value of rapeseed meal.

B. napus seeds are inherently dark brown in color. Yellow seed color was transferred into *B. napus* through interspecific hybridization and tested for agronomic performance (Rashid *et al.*, 1994; Rashid and Rakow, 1995; Rakow *et al.*, 1999; Relf-Eckstein *et al.*, 2003). Due to lower fiber contents, yellow-seeded *B. napus* has high oil. Meal from yellow-seeded canola has higher protein and lower fiber contents (Simbaya *et al.*, 1995).

Somers *et al.* (2001) developed random amplified polymorphic DNA (RAPD) markers for yellow seed *B. napus*. Liu *et al.* (2005) postulated in their study that seed color was controlled by three pairs of genes—a dominant yellow-seeded gene (*Y*) having an epistatic effect on the two independent dominant black-seeded genes (*B* and *C*), thereby inhibiting the biosynthesis of seed coat pigments. It is difficult to develop yellow-seeded canola hybrids because the genes responsible for this trait have to be transferred into both male and female inbreds, and the source pools from which inbreds are developed. If there was a single dominant gene available for the yellow seed trait, yellow-seeded hybrid development would be very simple.

In Canada, the canola crop is ready to swath from mid-August to mid-September. The crop is swathed at physiological maturity when the seeds in the bottom one-third of the pods on main raceme start changing color from green to dark brown. At this stage, seeds within pods of other branches are still green. As the swath lies in the field, chlorophyll within the seed is broken down and seed changes color from green to dark brown. If there is a frost, that causes plant tissue to die immediately, causing interruption in breakdown of chlorophyll. This causes premature death of seeds leaving them high in chlorophyll which ends up in the oil following crushing. The process of chlorophyll removal is an additional, expensive step that is unnecessary if the seeds are uniformly matured and have lowest possible green seed. In

Canada, at the point of delivery, a simple test verifies green seed number in the grain. If the number of green seed is higher than 2%, the crop is downgraded to Canada #2 instead of Canada #1 and farmer would receive lower value for the grain. This adds another breeding objective for the Canadian canola breeders: breeding for low chlorophyll and low green seed. Usually, later maturing varieties are more prone to higher green seed if not managed properly. At the same time there is variation among varieties because certain varieties consistently produce crops with low green seed content.

1.4.3 Improvement in disease resistance and insect resistance

Rapeseed and mustard have several important diseases and pests. The most common and widely occurring diseases and insects of canola and rapeseed in different countries are listed in Table 4. In Canada, Europe, and Australia, blackleg, caused by *L. maculans*, also known as stem canker or *Phoma* is the most important disease of canola. Currently, many of the commercial Canadian canola cultivars are rated “R” (resistant) for the most prevalent isolate of blackleg. The Australian isolates are the most virulent and have been reported to be present in a very small area in western Canada. There is tremendous genetic variation present in *B. napus* as far as

Table 4 List of most important rapeseed-mustard and canola diseases and insects in different countries

Country	Disease	Insects/pests
Canada	Blackleg (<i>Phoma lingam</i>) Sclerotinia (<i>Sclerotinia sclerotiorum</i>) Fusarium wilt (<i>Fusarium oxysporum</i> and <i>Fusarium avenaceum</i>)	Cabbage flea beetle (<i>Phyllotreta</i> spp.) Bertha armyworm (<i>Mamestra configurata</i>) Diamondback moth (<i>Plutella xylostella</i>)
China	Sclerotinia (<i>Sclerotinia sclerotiorum</i>) Turnip mosaic virus	Aphids (<i>Myzus persicae</i> , <i>Lipaphis erysimi</i> , <i>Brevicoryne brassicae</i>) Weevil (<i>Ceutorhynchus asper</i>) Diamondback moth (<i>Plutella xylostella</i>)
India	Alternaria (<i>Alternaria brassicae</i>) White rust (<i>Albugo candida</i>) Downy mildew (<i>Perenospora parasitica</i>)	Aphid (<i>Lipaphis erysimi</i>) Mustard saw fly (<i>Athalia proxima</i>) Painted bug (<i>Bagrada cruciferarum</i>)
Europe	Blackleg (<i>Phoma lingam</i>) Sclerotinia (<i>Sclerotinia sclerotiorum</i>) Light leaf spot (<i>Pyrenopeziza brassicae</i>)	Pollen beetle (<i>Meligethes aeneus</i>) Seedpod weevil (<i>Ceutorhynchus assimilis</i>) Cabbage stem flea beetle (<i>Psylliodes chrysocephala</i>)
Australia	Blackleg (<i>Phoma lingam</i>) Sclerotinia (<i>Sclerotinia sclerotiorum</i>) Damping off (<i>Rhizoctonia</i> spp., <i>Pythium</i> spp., <i>Fusarium</i> spp.)	Earth mites (<i>Halotydeus destructor</i> , <i>Penthaeus</i> spp.) Lucerne flea (<i>Sminthurus viridis</i>) False wireworm (<i>Isopteron punctatissimus</i> , <i>Adelium</i> spp.)

resistance is concerned. Also, *B. juncea* and *B. nigra* are mostly tolerant to blackleg, making them good sources of resistance. Plieske *et al.* (1998) concluded that the B genome provided strong, monogenic dominant resistance to blackleg. *Phoma* resistance is classified into two categories: (a) seedling resistance or cotyledon resistance, which is controlled by a few major genes and (b) stem resistance or adult plant resistance, which is controlled by many genes. The identification of genes responsible for race-specific resistance (cotyledon resistance) was reported (Rouxel *et al.*, 2003). Resistance caused by a major gene (seedling resistance) is not durable and can break down when used in varieties grown on a large scale. In Australia, resistance to blackleg caused by a single dominant gene was introduced in commercial cultivars in 2001, but it broke down within a short period of time. Adult plant resistance is complex and governed by several genes (Zhu and Rimmer, 2003). In a breeding program, it is desirable to utilize adult plant resistance since it is durable.

Sclerotinia stem rot, caused by *Sclerotinia sclerotiorum* is another important disease of canola that affects canola cultivation in major markets. In China, continuous and widespread presence of *Sclerotinia* in an environment conducive to disease development has forced breeding programs to develop tolerant varieties. In *B. napus*, there has been very little genetic variation available for resistance to *Sclerotinia*, however, over the years, through methodical screening and well-managed breeding, rapeseed varieties with improved resistance have been developed in China (Wang *et al.*, 2003a). *Sclerotinia* fungus also attacks other two important oilseeds, soybeans and sunflower. The screening for disease is very tedious and inheritance is very complex. Zhao and Meng (2004) identified six QTLs associated with this disease resistance of which three were associated with leaf resistance explaining 40.7% variation while the other three were associated with mature plant resistance explaining 49% of phenotypic variation.

In India, *Alternaria* blight caused by *Alternaria brassicae* is a devastating disease attacking the *B. juncea* crop in many parts of the country. It is reported that there is resistance available in other related species (Siemens, 2002). Klewer *et al.* (2003) reported transfer of *Alternaria* resistance from *S. alba* and other related species into *B. napus*. Although, there are very well-established screening techniques and natural conditions available, no

commercial *B. juncea* variety is available, which carries a high degree of tolerance to this disease. *Alternaria* blight is not a serious canola disease in Canada, Europe, and Australia.

Fusarium wilt is not a major disease in Canada. It was first reported in 2002 in some of the Canadian commercial canola varieties. It is easy to screen breeding material if the screening nursery is in the right environment. Most of the current commercial canola varieties in Canada are resistant to this disease.

Downy mildew caused by *Peronospora parasitica* is another important disease in *B. juncea* in India. This disease is not a serious problem of canola in Canada, Europe, and Australia. Resistance sources are available in *B. napus* and *B. juncea*. White rust is caused by *Albugo candida* and it is more prevalent in *B. rapa* and *B. juncea*. It is not a serious disease in Canada. Currently, all commercial *B. napus* varieties in Canada are resistant to white rust.

Flea beetle, *Phyllotreta cruciferae* (Goeze), is a serious insect of canola in western Canada. The damage is usually severe at cotyledon stage and at seedling stage. Feeding damage can result in complete death of young seedlings, severely reduced growth, and delayed crop establishment resulting in lower seed yield. Mechanism of resistance to flea beetle in *S. alba* has been reported (Bodynaryk and Lamb, 1991). Elliott and Rakow (1999) observed that flea beetle damage was least in *B. carinata* and *S. alba* lines and it was greatest in *B. juncea* and *B. rapa* lines. There is not complete *B. napus* resistance source available for breeding.

The cabbage seedpod weevil (*Ceutorhynchus obstrictus*) was introduced to North America from Europe about 70 years ago. It was first found infesting canola in southern Alberta in 1995 and since then, the weevil has spread to central Alberta and southwestern Saskatchewan. Canola, brown mustard, cole crops (e.g., cabbage, broccoli, cauliflower) and cruciferous weeds (e.g., wild mustard, flixweed, stinkweed) are all hosts to this insect. Cabbage pod weevil, also known as seedpod weevil, is a very destructive insect and causes a lot of damage to the crop in warmer conditions. *S. alba* (yellow mustard) is known to carry resistance against this insect. Dosdall and Kott (2006) successfully transferred resistance from *S. alba* into *B. napus* lines.

There are three aphid species that attack rapeseed mustard: (1) Indian mustard aphid (*Lipaphis*

erysimi), (2) cabbage aphid (*Brevicoryne brassicae*), and (3) green peach aphid (*Myzus persicae*). Of these, mustard aphid is a very devastating insect of rapeseed and mustard in India. Cabbage aphid and green peach aphids sometimes infest canola in Australia. Sekhon and Ahman (1992) described source of resistance in *B. juncea*, *B. napus*, and other species against mustard aphid. Also morphological, anatomical, and biochemical characteristics of resistant *Brassica* plants are described in detail. Kanrar *et al.* (2002) reported the development of a transgenic Indian mustard (*B. juncea*) line with resistance to Indian mustard aphid. Gowers and Christy (1999) were able to transfer aphid resistance from *B. oleracea* to *B. napus*. Aphid infestation is not a serious problem in canola in Canada.

Diamondback moth (*Plutella xylostella*) is another canola insect in Western Canada and feeds on all *Brassica* plants. Although, the diamondback moth is found throughout Western Canada, its damage varies from year to year. In their study, Andrahennadi and Gillott (1998) found that some of the varieties of *B. juncea* showed resistance to diamondback moth.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Conventional breeding can work for any trait as long as there is genetic variation available and it is possible to evaluate and select the trait in question. Usually, the traits for which there is little genetic variation initially could be improved slowly once the selection pressure is applied. The development of *Sclerotinia* tolerant rapeseed varieties is a good example, as there was very low level of tolerance available initially; however, after continuous breeding and selection for resistance, the level of tolerance increased. There are various methods of plant breeding that could be applied to increase the frequencies of desired alleles in breeding populations. As the frequencies of desired alleles increase, the level of expression for that trait would automatically improve.

For many traits in *B. napus* and *B. juncea*, there is sufficient genetic variation and it is possible to improve the traits through well-managed breeding, therefore, a transgenic approach does not make economic sense. Also, one has to remember that a transgenic approach is tedious that requires a

lot of developmental work, isolating, and cloning gene and then transforming plants. There is tremendous work involved in identifying the most desirable event once the plants are transformed and several events are developed. Data generation for regulatory approval is also very costly and time consuming, therefore, a transgenic approach can not be used for every trait. The trait has to have high economic value, very low or nonexistent genetic variation, and low possibility of genetic improvement through conventional plant breeding.

Table 5 lists all the important traits in spring and winter form of *B. napus* and *B. juncea* as they are the major oilseed crops. Some of these traits may not apply to *B. juncea*. Only the economically important diseases and insects are listed in the table, although there are many more diseases and insects that attack oilseed *Brassica*. The traits for herbicide resistance are listed in this table, but these are already developed and are incorporated into commercial material with very high success rate. There are traits with reasonably good genetic variation, yet the rate of genetic progress can be slow. This is because the trait is either difficult to screen and score or expensive to evaluate and has high environmental influence with low heritability. Yield is a good example of this as it requires multiple locations of replicated testing over several years in order to identify suitable genotypes making this an expensive trait to evaluate. Also, breeding priority has to be taken into consideration. The trait may have decent genetic variation and it would be easy to make genetic progress, but if the breeding priority is low, the trait would not be listed as one of the breeding objectives. White rust screening of *B. napus* genotypes in Canada fits this example. Transgenic approach has been reported for many traits in the literature, but its application and commercialization would always be determined by economic and socio-political aspects, which would be out of control of scientists.

2. DEVELOPMENT OF TRANSGENIC OILSEED BRASSICAS

The topics covered in this section have been extensively reviewed (Poulsen, 1996; Earle and Knauf, 1999; Palmer and Keller, 2002; Cardoza

Table 5 List of important *B. napus* and *B. juncea* traits and their priority for transgenic work

Trait	Genetic variation ^(a)	Feasibility of conventional breeding	Breeding priority	Rate of possible genetic progress	Need for transgenic approach
Yield	7	Yes	High	Low	
Pod numbers per plant	7	Yes	Medium	Moderate

and Stewart, 2004; Pua and Lim, 2004), thus readers are also referred to these articles.

2.1 Transgenic Traits in Oilseed Brassicas

Genes isolated from microbes, animals, plants, and in particular the model plant *Arabidopsis thaliana*, have been used as a source of candidate genes for transforming oilseed Brassicas. The promoter used to drive the selectable marker or the genes of interest has been, in most cases, the 35S promoter from the tobacco mosaic virus, but spatial and

temporal expression of a target gene is usually driven by tissue or developmental phase-specific promoters. The use of the 35S promoter, when placed next to a tissue-specific promoter, can be problematic, because the strong promoter can “read through” and lead to “leaky” expression of the target gene that is intended to be tissue specifically expressed (Jagannath *et al.*, 2001). This problem can be alleviated by replacing the 35S promoter with a weaker one or by insertion of a spacer DNA as an insulator. The nos terminator from *Agrobacterium* has been widely used as a transcriptional terminator.

2.1.1 Herbicide tolerance

This subject is comprehensively reviewed by Warwick and Miki (2004) and readers are referred to this article. Herbicide resistance was among the first transgenic traits to be developed and commercialized in canola and other crops. This can be largely attributed to the relatively simple genetic manipulation (single gene control), the existing background knowledge of the physiological and biochemical characteristics of herbicide actions, the relatively more advanced tissue culture and plant regeneration technologies in Brassicas, and the enormous importance of weed control in crop production. Herbicide resistant transgenic canola commenced commercial production in 1995, and has since been rapidly and widely adopted by growers in Canada. There are four classes of herbicides for which transgenic canola has been obtained: glufosinate ammonia resistance conferred by the *bar* (DeBlock *et al.*, 1989) and *pat* genes (Oelck *et al.*, 1991); glyphosate (Roundup) resistance conferred by a mutant allele of the gene encoding 5-enolpyruvylshikimate-3-phosphate (EPSP) synthase (Parker *et al.*, 1991); resistance to chlorsulfuron and related herbicides conferred by a mutant allele of the gene for acetolactate synthase (ALS) (Miki *et al.*, 1990); and resistance to bromoxynil by a nitrilase enzyme gene (Freyssinet *et al.*, 1996). Glyphosate (N-[phosphonomethyl]glycine) is the active ingredient of the commercial herbicide Roundup. It acts as an inhibitor of EPSP synthase, which functions in the aromatic amino acids biosynthesis pathway located in the chloroplast. The pathway is also present in bacteria and fungi but not in mammals or birds (Monsanto, 2002). Glyphosate resistant (Roundup Ready[®]) canola was obtained by transformation of *B. napus* cv. Westar with two genes in a single transfer DNA (T-DNA) vector via *Agrobacterium*-mediated transformation, *cp4 epsps* and *goxv 247* (Monsanto, 2002). The *cp4 epsps* gene encodes a bacterial form of EPSP synthase from *Agrobacterium* strain CP4, which is naturally tolerant to glyphosate. The chloroplast transit peptide sequence of the *Arabidopsis* EPSP synthase gene was fused to the gene to ensure transport into the chloroplast and processing of the bacterial enzyme. The second gene, *goxv 247* from *Ochrobacterium anthropi* strain LBAA, encodes a form of glyphosate oxidase (GOX),

which catalyzes the breakdown of glyphosate into the nontoxic products glyoxylic acid and aminomethylphosphonic acid (AMPA). The *goxv 247* gene was fused to the chloroplast transit peptide sequence from the *Arabidopsis* ribulose biphosphate carboxylase (*rbc*) small subunit gene, *SSUIA-CTP1*. Both chimeric genes were driven by the 35S promoter and terminated with the E9 pea *rbc* small subunit gene (*rbcSA*) 3' region. Thus, two mechanisms of resistance are working in these commercial lines: an alternate EPSP synthase with reduced herbicide binding and a novel enzyme for degradation of the herbicide. The line was first given regulatory approval in 1995 in Canada. Subsequently, the trait was introduced into *B. rapa* varieties via conventional crossing (CFIA 2002).

Phosphinothricin (PPT; marketed as glufosinate-ammonium, Basta, Ignite, Liberty, Finale) is an analogue of L-glutamic acid and a strong inhibitor of glutamine synthetase (GS). GS is the only enzyme in plants that can catalyze the assimilation of ammonia into glutamic acid, which is a donor for almost all nitrogenous compounds in plants. Inhibition of GS by PPT may lead to the accumulation of ammonia and subsequently cell death. Two genes, *pat* and *bar*, were used for generating transgenic canola. The *pat* gene encodes PPT N-acetyltransferase from *Streptomyces viridochromogenes* (Wohlleben *et al.*, 1988). The acetyl transferase acetylate PPT detoxifies it. The homolog of the gene from *Streptomyces hygroscopicus* is called *bar* (Thompson *et al.*, 1987). They share approximately 87% identity at nucleotide level and require some codon optimization for expression in plants. The *pat* gene driven by a strong constitutive promoter was introduced into *B. napus* cv. Topas by *Agrobacterium*-mediated transformation of microspore-derived embryos (Oelck *et al.*, 1991). The transgenes was later crossed into other *B. napus* and *B. rapa* varieties for field evaluation (Kumar *et al.*, 1998) and commercial production (CFIA 2002). The same construct was also introduced directly into *B. napus* cv. Excel (CFIA 2002). These lines have been approved for use in human oil consumption and livestock meal in Canada, the United States, Japan, and Australia (Agbios, 2002). The *bar* gene was first introduced into *B. napus* cv. Drakkar (De Block *et al.*, 1989) and subsequently introduced

into a number of cultivars. It has also been approved in Canada, the United States, and Japan (Agbios, 2002).

The oxynil herbicides, bromoxynil and ioxynil, inhibit photosystem II electron transport in plants. The *bnx* gene encoding the bromoxynil nitrilase, which catalyzes the conversion of bromoxynil into 3,5-dibromo-4-hydroxybenzoic acid, was isolated from *Klebsiella pneumoniae* ssp. *Ozaenae* (Stalker and McBride, 1987). The gene under the control of the 35S promoter was introduced into *B. napus* cv. Westar by *Agrobacterium*-mediated transformation and high level of resistance was observed (Freysinet *et al.*, 1996). The transgenic line has been approved for commercial production in Canada and Japan (Agbios, 2002; CFIA 2002).

At least four classes of herbicides, i.e., sulfonylureas, imidazolonones, triazolopyrimidines, and pyrimidinyl thiobenzoates, target ALS or acetohydroxy acid synthase (AHAS), a regulatory enzyme in the branched-chain amino acid biosynthesis pathway in chloroplasts (Singh and Shaner, 1995). The enzyme appears to be encoded by a small gene family (Rutledge *et al.*, 1991). A variety of mutant ALS alleles have been identified and characterized, which confer resistance to a specific herbicide class or to multiple classes (Guttieri *et al.*, 1996). In *B. napus*, a mutant AHAS3 gene, *ahas3R*, was cloned, which has a single mutation responsible for multiple herbicide resistance (Hattori *et al.*, 1995). A mutant AHAS3 gene, *csr1-1*, has been introduced into canola, *B. napus* cvs. Profit (Miki *et al.*, 1990) and Westar (Blackshaw *et al.*, 1994), under control of either the 35S promoter or its native promoter. The *csr1-1* gene was isolated from *A. thaliana* known to confer increased resistance to the sulfonylurea herbicide chlorsulfuron (Haughn *et al.*, 1988). Resistance to herbicides was demonstrated in greenhouse and field tests, but these transgenic canola lines have not been commercialized.

2.1.2 Insect resistance

The topic has been reviewed by many authors, including Estruch *et al.* (1997), Jouanin *et al.* (1998), Schuler *et al.* (1998), Hilder and Boulter (1999), Bruenn (2000), and Earle *et al.* (2004). Two main types of transgenic insect resistant oilseed

Brassicas have been developed to date: those expressing *Bacillus thuringiensis* (*Bt*) genes and those expressing proteinase inhibitor (PI) genes. None of the transgenic lines developed have been approved for commercial production.

A wide range of insects can feed on Brassicas, targeting their roots, stems, leaves, and reproductive parts. At least seven orders of insects have species that feed on Brassicas (Earle *et al.*, 2004). Among these, diamondback moth (*P. xylostella*) may be the most devastating pest of Brassicas worldwide. Control strategies need to take into account the various feeding mechanisms displayed by different insects. Genes encoding insecticidal crystal proteins (ICPs) from the soil bacterium *Bt* have been most commonly used in most transgenic studies of insect resistance. One of the attractive features of *Bt* for insect control is its specificity. Different bacterial strains produce different ICPs, each of which has specificity for insects in different orders. This offers the possibility to control certain types of insects without harming others. Another major feature of *Bt* is that there are many ICPs that have unique modes of action or target sites in insects. This offers the potential to control some pests that have developed resistance to other insecticides.

Bt genes have been introduced into oilseed Brassicas (Stewart *et al.*, 1996; Li *et al.*, 1999; Halfhill *et al.*, 2001; Kuvshinov *et al.*, 2001; Winterer and Bergelson, 2001; Wang *et al.*, 2005b). The synthetic *cry1Ac* gene with codon optimized for better expression in plants was used for most studies. In some cases, only one *Bt* gene is transformed; while in some other cases a reporter such as the β -glucuronidase (GUS; Kuvshinov *et al.*, 2001) or the green fluorescent protein (GFP) (Halfhill *et al.*, 2001) was co-transformed. The GFP marker may be useful for selection of transformants, bypassing the need for antibiotics or herbicides, and may also be useful in monitoring the movement of the linked *Bt* transgene beyond the original transgenic crop (Halfhill *et al.*, 2001; Stewart, 2006). In a couple of studies, transgenic *B. napus* plants containing a *Bt* gene and another gene for enhanced resistance were generated. Winterer and Bergelson (2001) crossed *B. napus* cv. Westar carrying either a *cry1Ac* gene or potato PI (*P12*) gene and recovered homozygous lines carrying both the genes. Wang *et al.* (2005b) introduced *aroA-M12*, an EPSPS

gene, and a *Bt*slm recombinant gene encoding *Bt* toxin gene, into *B. napus* cv. Xiangyou No. 15. The 35S promoter was used to drive the *Bt* genes in almost all the works, and in only one case the mannopine synthase promoter (also a constitutive promoter) from *Agrobacterium tumefaciens* was used (Winterer and Bergelson, 2001). *Agrobacterium*-mediated transformation of seedling explants was employed in these reports using antibiotics or herbicides for tissue selection.

Significant variations of *Bt* protein expression level is common, as it is for other transgenes, and the development of large number of transgenic lines were necessary for selecting better expressors. The documented *Bt* protein levels range from as low as 0.0005% to a maximum of approximately 0.4% of total soluble protein (TSP) (Stewart *et al.*, 1996). Transgenic plants are tested by bioassays using selected insects on detached leaves and/or on whole plants. The diamondback moth has served as a primary choice of insects because of its agricultural importance and because some populations of these moths have developed resistance to some *Bt* proteins in the field due to exposure to *Bt* sprays. It has been demonstrated that the susceptible moths are well controlled by plants with high expression. In many cases there has been no follow-up to the initial work reported. However, some of the transgenic lines generated have been used in various confined greenhouse and field studies.

PIs are usually found in seeds or other storage tissues, where they can act to disrupt the digestive enzymes used by insects to break down proteins ingested and thus offer the potential to control insects. Different insects have different primary proteinases and are sensitive to different PIs. Therefore understanding the biochemistry of the interaction and choosing the right combination are the keys for successful control. Transgenic *B. napus* plants have been produced with PI genes from different plant sources: *MTI-2* from white mustard (*S. alba*) (DeLeo *et al.*, 2001); *PI-2* from potato (Winterer and Bergelson, 2001); *OCI* from rice (Girard *et al.*, 1998a, b); and *CII* from soybean (Jouanin *et al.*, 1998). The spring cultivar Drakkar was used in all the studies except in one case Westar was used (Winterer and Bergelson, 2001). Only lower levels of PI protein (0.15–0.25% TSP) were expressed in the *MTI-2* lines. These

plants were tested against larvae of various insects and *P. xylostella* was the most sensitive with high mortality and retarded development. No significant impact on other insects was found. Expression of the *PI-2* gene (0.002–0.01% TSP) did not retard the growth rate of *P. xylostella* moth and actually led to a slightly more leaf damage. Even when *Bt* and *PI-2* are co-expressed, insect control was not reduced rather enhanced. Similar negative results were found for the *OCI*, *CII*, as well as the *OCI-CII* double transgene lines. There are a few possible explanations for these results, including the likely mismatch between the insects tested versus the transgenic lines, the possibility of insect adaptation to the PIs, and the paradoxical effects that may be seen when expression of PIs is low (Earle *et al.*, 2004).

Other than *Bts* and PIs, there have been other efforts to control insect pest of *B. napus*. Recently, Wang *et al.* (2005a) generated *B. napus* plants transgenic for two genes, a chitinase gene encoding insect-specific chitinase from *Manduca sexta* and a scorpion insect toxin gene from *Buthus martensii* Karsch. Fifty-seven transgenic lines were obtained and inoculated with diamondback moths larvae using *in vitro* leaf-feeding assay. Significant insecticidal activity was observed and the activity was well correlated with the levels of proteins encoded by the two transgenes estimated by ELISA. These are interesting results, particularly due to the fact that some diamondback moths have developed resistance due to the wide use of *Bt*. Resistant transgenic plants containing new genes or novel combinations of genes may slow down and eventually minimize the development of resistance by insects.

2.1.3 Disease resistance

Oilseed Brassicas are particularly subject to attack by various fungal pathogens, including ascomycetes *A. brassicae*, *A. brassicicola*, *L. maculans*, *Pyrenopeziza brassicae*, *S. sclerotiorum*, and *Verticillium longisporum*, the myxomycete *Plasmodiophora brassicae*, and the oomycete *A. candida* (Dixelius *et al.*, 2004). The loculoascomycete *L. maculans* (Desm.) Ces. et de Not. is the most important pathogen of oilseed Brassicas worldwide, causing stem canker or blackleg disease. For this reason a number of

efforts have been made to control the disease using a transgenic approach. Genes used for these studies include a tomato chitinase gene (Grison *et al.*, 1996), a pathogenesis-related peroxidase of *Stylosanthes humilis* (Kazan *et al.*, 1998), a pea defense gene *DDR206* (Wang *et al.*, 1999, 2001), the R gene *Cf9* from tomato (Hennin *et al.*, 2001a, b, 2002), and a novel antimicrobial peptide (Kazan *et al.*, 2002). Certain degrees of resistance were obtained with these transgenes. Particularly, the transgenic oilseed rape constitutively overexpressing a chimeric chitinase gene gave field tolerance not only to *L. maculans*, but also *P. brassicae*, and *S. sclerotinia*, the causal agents of stem rot and light leaf spot, respectively (Grison *et al.*, 1996). Furthermore, the first resistant gene named *Lm1* effective against *L. maculans* was cloned from *B. nigra* (Wretblad, 2002; Wretblad *et al.*, 2003). Transgenic *B. napus* plants expressing the *Lm1* gene exhibited resistance to PG2, PG3, and PG4 isolates. Stem rot caused by discomycete *S. sclerotiorum* (Lib.) de Bary is another common disease around the world. Transgenic oilseed Brassicas expressing an oxalate oxidase gene derived from *Hordeum vulgare* roots showed enhanced resistance to *Sclerotinia* sp. The enzyme destroys the oxalate, which is required for fungal infection (Thompson *et al.*, 1995). This is significant since no broadly-available, simple genetic source of resistance has yet been identified.

The plant immune response is best studied in the model plant *Arabidopsis* (Chisholm *et al.*, 2006). This model plant has been widely used for cloning and functional studies of defense-related genes and signaling pathways. It is expected that knowledge gained in the *Arabidopsis* system has the potential for application in Brassica crops. However, not all the defense mechanisms are conserved between the two species. For example, the *RPM1* resistance gene from *Arabidopsis* is missing in *B. napus* (Grant *et al.*, 1998). For this reason, international efforts on Brassica genomics have been initiated (www.brassicainfo.org). The genomics resources generated by these efforts have greatly facilitated the direct cloning of genes in Brassica, albeit a tremendously difficult job. Recently, significant progress has been made toward the map-based cloning of *LmRI* locus, which controls seedling resistance to the blackleg fungus *L. maculans* in the *B. napus* cultivar Shiralee (Mayerhofer *et al.*, 2005).

2.1.4 Abiotic stress tolerance

Arabidopsis has been an excellent model plant for studying of abiotic stress responses and biotechnology (Zhang *et al.*, 2004). During the past decade, great progress has been made with this model system in unraveling the abiotic stress signal transduction (salt, cold, and drought stress), and these new insights have provided promising novel approaches to engineer plant tolerance to abiotic stresses. A number of genes have been demonstrated to be effective in conferring stress tolerance when overexpressed or knocked down in transgenic *Arabidopsis* plants. Some of these genes have been shown to be conserved in crop species including *B. napus* (Zhang *et al.*, 2004).

The potential of manipulating ion transporters to improve ion homeostasis is well recognized. For example, several classes of transporters are required in regulating sodium homeostasis under salt stress. The influx of Na^+ is controlled by *AtHKT1*, a low affinity Na^+ transporter (Rus *et al.*, 2001), and other nonselective cation channels, while the efflux is controlled by Salt Overly Sensitive 1 (*SOS1*), a plasma membrane Na^+/H^+ antiporter (Shi *et al.*, 2000). Vacuolar membrane ion transporters, such as the tonoplast Na^+/H^+ antiporter *AtNHX1* (Apse *et al.*, 1999; Gaxiola *et al.*, 2001), also play a vital role in regulating cytoplasm Na^+ homeostasis by sequestering Na^+ ions in the vacuole. It appears that coordination exists between the transporters in the tonoplast and plasma membranes through other components of the *SOS* pathway, albeit the mechanism is not completely understood (Chinnusamy *et al.*, 2006). It is commonly believed that maintaining a low cytosolic Na^+ concentration is essential to achieve salt tolerance and can be achieved by restricting inflow, increasing outflow, or increasing vacuolar sequestration of Na^+ . Thus, theoretically, increasing plasma membrane Na^+ exporters and tonoplast Na^+ importers and/or restricting the amount of Na^+ influx by lowering the amount of plasma membrane Na^+ importers should suffice. Indeed, a number of successes have been documented when these strategies were used (Zhang *et al.*, 2004). For example, increased expression of the *Arabidopsis* tonoplast membrane Na^+/H^+ antiporter, *AtNHX1*, under a strong constitutive promoter was reported to result in salt-tolerant *Arabidopsis* (Apse *et al.*, 1999) and

B. napus (Zhang *et al.*, 2001). The transgenic *B. napus* plants were able to grow, flower, and produce seeds in the presence of 200 mM sodium chloride. Although the transgenic plants grown in high salinity accumulated sodium up to 6% of their dry weight, growth of these plants was only marginally affected by the high salt concentration. Moreover, seed yields and the seed oil quality were not affected.

In contrast to ion homeostasis, a plant's adaptation to cold and drought is to a greater extent under transcriptional control, and some processes are regulated by abscisic acid (ABA), while others are ABA-independent (Shinozaki *et al.*, 2003; Chinnusamy *et al.*, 2004). For these reasons, it is not surprising that transcription factors (TFs) represent one of the best targets for engineering plants to achieve enhanced cold and drought tolerance. Even so, not all TFs involved in the cold and drought signal transduction are suitable targets. The *CBF* genes have been successfully used to engineer abiotic stress tolerance in a number of different species (Zhang *et al.*, 2004). *CBFs* are a class of AP2 TFs that plays a central role in both the ABA-dependent and ABA-independent pathways. Expression of all *CBF* genes in *Arabidopsis* is low under normal growth condition but increases within several minutes after cold or drought stress. In addition, the DNA-binding activity of some *CBFs* can also be modulated by temperature. The orthologous genes of *CBF* have been found in most crop plants examined so far, including *B. napus*. Constitutive overexpression of the *Arabidopsis CBF* genes in canola results in increased freezing tolerance (Jaglo *et al.*, 2001) and drought tolerance (Zhang *et al.*, 2004; Zhang *et al.*, unpublished). In these studies, it was discovered that ectopic overexpression of the *CBF* genes in plants produced, in addition to increased stress tolerance, dark-green, dwarfed plants. To overcome these problems, stress-inducible promoters that have low background expression under normal growth condition have been used in conjunction with the *CBF* genes to achieve increased stress tolerance in tobacco plants without the retarded growth (Lee *et al.*, 2003).

Another biotechnological target for improving plant drought tolerance is the genetic manipulation of the stress response to ABA. ABA modulates stomatal aperture to reduce

transpirational water loss. Under water stress conditions, the endogenous level of ABA increases, which, through a complex signaling cascade, results in stomatal closure (Blatt, 2000). When water relations return to optimal conditions for growth, ABA concentration decreases to reverse the process. Thus, the ability to regulate ABA synthesis and response makes this hormone an excellent target for improving drought tolerance in crop species. A number of genes have been identified, through genetic screens, which either increase or decrease the plant's response to ABA (Finkelstein *et al.*, 2002). Of these, *ERA1* and *ABH1* are of particular interest, as loss-of-function alleles of these genes increase sensitivity of the guard cells to ABA (Cutler *et al.*, 1996; Pei *et al.*, 1998; Hugouvieux *et al.*, 2001). As a consequence, *era1* or *abh1* mutants show reduced wilting during drought stress. In the presence of exogenous ABA, the *era1* leaves display the tightest stomatal aperture closure. *ERA1* encodes the β -subunit of *Arabidopsis* farnesyltransferase (AtFTB), suggesting that a negative regulator of ABA sensitivity must be farnesylated to modulate ABA response in *Arabidopsis* (Cutler *et al.*, 1996). All plant farnesyltransferases identified to date consist of heterodimer of an α - (AtFTA) and β -subunit, each of which belongs to a single-gene family. Loss of function of *ERA1* in *Arabidopsis* results in reduced water loss, but also causes severe pleiotropic phenotypes in growth and development (Bonetta *et al.*, 2000). Interestingly, further transgenic studies demonstrated that downregulation of either AtFTA or AtFTB, by antisense transgene approach, resulted in both increased ABA sensitivity and improved drought stress tolerance in *Arabidopsis* (Wang *et al.*, 2005c). Furthermore, use of a drought-inducible *Arabidopsis rd29A* promoter to drive the antisense expression of AtFTB in canola conferred similar drought protection in this species (Wang *et al.*, 2005c). Transgenic canola plants showed enhanced ABA response during seedling development. In addition, under drought conditions, ABA-hypersensitive plants showed greater reduction in stomatal conductance and leaf transpiration than the parental nontransgenic plants. It was also demonstrated that the downregulation of targeted gene expression driven by this drought-inducible promoter is a conditional, reversible process that is controlled by the available soil water content.

More importantly, results obtained from three consecutive years of field trials indicated that in the field under well-irrigated conditions, these transgenic plants showed similar or greater seed yield than the parental plants. When irrigation was reduced at the peak of flowering, transgenic canola showed significantly greater seed yield than the parental control (Wang *et al.*, 2005c).

2.1.5 Fatty acid modification

Transgenic manipulation of storage lipid biosynthesis represents some of the most successful cases of metabolic engineering in oilseed crops. Research in this field has benefited greatly from the use of *Arabidopsis* as a model system for study of plant lipid biochemistry. Based on genomic information from *Arabidopsis* there are about 600 genes implicated in lipid metabolism, many of which are potential targets of genetic manipulation of storage lipid deposition in seeds. For a detailed description of the metabolic steps and enzymatic components involved in plant fatty acid and glycerolipid synthesis, readers are referred to articles by Ohlrogge and Browse (1995), Ohlrogge and Jaworski (1997), and Weselake (2005). A review by Thelen and Ohlrogge (2002) is recommended for highlights of achievement in seed oil biotechnology in Brassica and other major oilseed crops.

Currently, the Brassica seed oil industry is still primarily focused on edible oil. Improving oil profile for human health has been a predominant theme. Direct downregulation of some of the fatty acid biosynthesis enzymes and introduction of novel fatty acid modification enzymes have resulted in large compositional changes in the fatty acid compositions of seed oil. In order to reduce the need of industrial dehydration that causes the production of trans-unsaturated fatty acids, high stearic oil is preferred for the production of solid fat, such as margarines. Research through antisense the stearyl-acyl-ACP desaturase gene in Brassica resulted in an increase of stearic acid to a level of up to 40% (Knutzon *et al.*, 1992). Since higher monounsaturated fatty acid is required for a desired oil profile, co-suppression of the $\Delta 12$ desaturase has been employed, leading to an oleic level at 89% in seed oil (Stoutjesdijk *et al.*, 2000). Some fatty acids, particularly γ -

linolenic acid (GLA), have documented beneficial effects when used as a nutritional supplement in humans. GLA can be produced from linoleic acid through desaturation mediated by the $\Delta 6$ desaturase. Traditionally, borage has been the main source for GLA. In order to overcome the yield limitation of borage, research has been conducted to introduce a $\Delta 6$ desaturase gene originated from the oleaginous fungus, *Pythium irregulare* into Brassica species, and the transgenic *B. juncea* lines were capable of producing GLA up to 40% of the total fatty acids (Hong *et al.*, 2002). Plant-based production of very long chain polyunsaturated acid (VLCPUFA), particularly eicosapentaenoic acid (EPA, C20: A5, 8, 11, 14, 17) and docosahexaenoic acid (DHA, C22: A4, 7, 10, 13, 16, 19) as a nutraceutical supplements, offers not only economic benefits but also addresses the concern on the ever-decreasing fish stocks from which these fatty acids are primarily obtained. Major enzymatic components required for fatty acid desaturation and elongation to the formation of DHA have now all been identified. Using a series of transformations involving nine different genes, a group at the Bioriginal Food and Science Corporation, achieved an important milestone of producing transgenic *B. juncea* with EPA level of up to 15% of seed oil (Wu *et al.*, 2005).

Large scale and low cost production of specialty oil as renewable industrial feedstocks in Brassica has been a commercial-driven research goal for quite some time (Kinney, 1998). One of the most notable successes of such an endeavor is that of high laurate *B. napus* produced by Calgene. Expression of a 12:0-acyl-ACP thioesters isolated from California bay laurel (*Umbellularia California*) in canola seeds resulted in highly saturated canola oil, known as BTE canola, with lauric content surpassing 50% of the seed oil (Voelker *et al.*, 1996). Subsequent studies revealed that the laurate was found almost exclusively at the sn-1 and sn-3 positions of the glycerol backbone due to an apparent substrate specificity limitation of the lysophosphatidic acyltransferase (LPAAT) in Brassica, which acylates the sn-2 position. To further improve laurate content, a coconuct 12:0-CoA-prefering LPAAT was introduced into the BTE expressing lines, which led to the production of trilaurin, and a level of laurate approaching 67% in seed oil (Knutzon *et al.*, 1999). In a similar study using an acyl-ACP thioesterase gene

from the Mexican shrub *Cuphea hookeriana*, which accumulates up to 75% caprylate (8:0) and caprate (10:0) in its seed oil, transgenic *B. napus* plant accumulating 11 and 27 mol% of these two fatty acids in seed oil have also been reported (Dehesh *et al.*, 1996).

Genetic manipulation of *B. napus* for the purpose of producing the very long chain erucic acid used in plastic film manufacture and the lubricant and emollient industries has sparked research interests for more than a decade. The main goal of transgenic improvement is to increase the level of erucic content, which is currently found around 45% in some of the HEAR cultivars. Two enzymatic steps crucial for the biosynthesis of erucic acid have so far been specifically targeted: the fatty acid elongase FAE1 and the sn-2 fatty acyltransferase LPAAT. FAE1 encodes for a seed-specific condensing enzyme of the fatty acid elongation enzyme complex responding for extending the 18 carbon fatty acid to that of 22. Seed-specific expression of the *Arabidopsis* FAE1 gene in a HEAR germplasm led to increases in the proportions of erucic from 48% to 53% among the best greenhouse grown transgenic lines. Substrate specificity of the sn-2 acyltransferase LPAAT that is incapable of incorporating long chain fatty acids into triacylglycerols is another limiting factor of erucic acid content. When a mutant allele of the yeast LPAAT, *SLC1* was introduced into cultivars of *B. napus* Hero and Reston, the resulting transgenic plants showed increases in both overall proportions and the amounts of erucic acid (Zou *et al.*, 1997; Katavic *et al.*, 2000). Similar strategy has also been applied to *B. juncea*, in which a FAE1 transcript level has resulted in increased erucic content (Kanrar *et al.*, 2006). In addition to transgenic technology, an asymmetric somatic hybridization approach using *B. napus* and *Crambe abyssinica*, an annual cruciferous oil crop with a high content of erucic acid, has also been shown to have potential for improving the amounts of erucic acid in *B. napus* (Wang *et al.*, 2003c).

2.1.6 Modification of other seed composition for improved nutrition

In oilseed Brassicas, the oil-free meal is a useful source of animal feed. There have been a number of efforts using transgenic approaches to improve the

nutritional value of seed meal. Oilseed Brassicas generally contain relatively low levels of essential amino acids such as methionine, lysine, and cysteine. Thus, attempts have been made to modify the protein composition and balance the amino acids proportion (deClercq *et al.*, 1990; Altenbach *et al.*, 1992; Kohno-Murase *et al.*, 1994, 1995; Denis *et al.*, 1995a, b; Falco *et al.*, 1995). Altenbach *et al.* (1992) generated transgenic canola plants expressing the methionine-rich 2S albumin protein precursor gene from Brazil nut, under the control of the phaseolin promoter. The methionine-rich protein was shown to be accumulated to 1.7–4% of the total seed protein and because of this the seed methionine content was increased to 33%. This work also suggests that the Brazil nut precursor protein can be processed and deposited correctly in canola. Using an antisense transgenic approach to downregulate the expression of the 12S seed storage protein cruciferin, Kohno-Murase *et al.* (1995) observed an increase in essential amino acids, methionine, lysine, and cysteine, 8%, 10%, and 32%, respectively. Cruciferin accounts for 60% of total seed proteins in *B. napus* and contains very low levels of the three essential amino acids. The total seed protein and lipid contents were not affected, so it is conceivable that the resources were redirected to enhance the synthesis of otherwise less abundant seed proteins, which may have a more balanced amino acids' composition, resulting in the increase of the content of the three essential amino acids. Falco *et al.* (1995) took a different approach, by manipulating the lysine synthesis pathway, to increase the content of the amino acids in transgenic canola seeds. The two key enzymes in the lysine biosynthesis pathway, aspartokinase (AK) and dihydrodipicolinic acid synthase (DHDPS), are regulated by end product feedback inhibition. To circumvent this normal feedback regulation, lysine feedback-insensitive bacterial DHDPS encoded by the *dapA* gene from *Corynebacterium*, was linked to a chloroplast transit peptide and expressed from a seed-specific promoter in transgenic canola seeds. As a result, more than 100-fold increases in the accumulation of free lysine in the seeds were obtained.

In addition to balanced amino acids composition, efforts have also been made to improve nutritional value of transgenic Brassica oilseeds by overexpression of carotenoids (Shewmaker *et al.*,

1999) and the introduction of phytase (Ponstein *et al.*, 2002). Carotenoids are a group of compounds derived from the five carbon isoprenoid precursor isopentenyl diphosphate, including α - and β -carotene, lycopene, and lutein. These compounds serve a variety of functions in mammals and humans. Amongst them, β -carotene is best known, which serves as a dietary precursor of vitamin A in the body. The carotenoid pathway has been elucidated since the 1960s and complementary DNAs (cDNAs) for most of the major enzymes have been cloned from both plant and microbial sources in the 1980s (Cunningham and Gantt, 1988). The first committed step in carotenoid biosynthesis is the condensation of two geranylgeranyl diphosphate moieties to give phytoene. The gene responsible for this reaction, phytoene synthase, has been cloned from a variety of microbial and plant sources. Phytoene synthase has been considered to be a regulatory point in the pathway. Shewmaker *et al.* (1999) produced *B. napus* transgenic plants overexpressing phytoene synthase gene *crtB* from the bacteria *Erwinia uredovora* in plastid. The phytoene synthase gene fused with the transit peptide of the pea small subunit of ribulose biphosphate carboxylase (rubisco) was under the control of a napin promoter for seed-specific expression, and plastid targeting. The resultant embryos from these transgenic plants were visibly orange and the mature seeds contained up to a 50-fold increase in carotenoids, predominantly α - and β -carotene with a significant amount of phytoene. Other metabolites in the isoprenoid pathway were also examined, and it was found that both tocopherol and chlorophyll were decreased. Unexpectedly, the fatty acid composition was also altered: oleic acid increased while linoleic and linolenic acids decreased.

Seeds are rich in phosphorus, but phosphorus is stored mainly in the form of phytate and it can not be utilized by monogastric animals because they lack the enzyme phytase in the digestive tract for phytate hydrolysis. Therefore, either exogenous phytase or phosphorus needs to be supplemented in the animal feed. This is costly both economically and environmentally, since the phytase production by fermentation is not cost effective, and phosphorus application and the undigested phytate will be released to the environment and cause pollution. Ponstein

et al. (2002) introduced the *Aspergillus niger* gene encoding phytase (*phyA*) into canola *B. napus*. The gene was under the control of the seed-specific cruciferin (*CruA*) promoter for overexpression in seeds. The cruciferin signal peptide was also incorporated into the expression construct to direct the secretion of the enzyme. Phytase expression in the T₁ seeds ranged from 0 U g⁻¹ to 600 U g⁻¹ seed. The transgenic trait has also been shown to be stable for up to four generations under greenhouse and field conditions.

2.1.7 Oilseed as bioreactor

In the past decade, there has been increasing interest and effort in producing recombinant proteins for industrial or biopharmaceutical uses in plants. The major advantages of the plant expression system are: (1) plants are free from potential human pathogen contamination and are thus considered relatively safe; and (2) large scale production in plants is cost effective. Oilseed Brassicas provide an inexpensive source of proteins. Attempts have been made to overexpress recombinant proteins in seeds, particularly in seed oil bodies for easy extraction and purification of the expressed protein. Lee *et al.* (1991) demonstrated that the maize oleosin gene driven by the promoter/terminator of a 2S albumin (napin) gene from Brassica was expressed and correctly targeted to seed oil bodies of transgenic *B. napus*. Soon after, Moloney *et al.* performed a series of studies and established the Brassica seed oil bodies as a vehicle for the production of recombinant proteins (van Rooijen and Moloney, 1995a, b; Parmenter *et al.*, 1995; Liu *et al.*, 1997; Chaudhary *et al.*, 1998; Kuhnelt *et al.*, 2003). First, they demonstrated that a fusion comprising a complete oleosin coding domain and a GUS coding sequence could be expressed specifically in the seeds of *B. napus*, and its product was correctly targeted with approximately 80% of the activity partitioning with oil bodies (van Rooijen and Moloney, 1995a). Recombinant oil bodies can be used to facilitate separation of a recombinant protein from other cellular proteins by flotation centrifugation. The target protein may then be released from the oil bodies by

cleavage with endoprotease and further purified (Kuhnel *et al.*, 2003). The fusion protein is stable in dry seeds for long periods. This demonstrates that foreign proteins other than oleosin can be correctly targeted to seed oil bodies. Further, the domains of oleosin required for correct targeting were mapped and the results indicate that both the N-terminal (1-47 amino acids) and central oleosin domain (48-113 amino acids, which make up a lipophilic core) are important for targeting to the oil body (van Rooijen and Moloney, 1995b). The expression system has been used successfully for the production of the leech anticoagulant protein hirudin (Parmenter *et al.*, 1995) and xylanase, an enzyme encoded by the *xynC* gene of rumen fungus *Neocallimastix patriciarum* (Liu *et al.*, 1997) in *B. napus*. The hirudin has also been expressed in *B. carinata*, an attractive alternative for the production of recombinant proteins (Chaudhary *et al.*, 1998), mainly due to the fact that it is not a crop in most of world, only in a localized area in Ethiopia and neighboring countries, it does not normally cross-pollinate with *B. napus*, thus avoiding transgene flow. All of these proteins retained their native biological activity.

Efforts have also been made to produce commercially useful biodegradable plastics in *B. napus* seeds (reviewed by Hanley *et al.*, 2000). The environmental benefit of such plastics is obvious, and their renewable nature is even more important in the long run. Plants use energy from sun to fix CO₂ and water to synthesize the plastic, which is then degraded back to CO₂ and water after use and disposal. Many bacterial species make polymerized carbon storage products from simple metabolic intermediates under limiting nutrient conditions (Madison and Huisman, 1999). These polymers have plasticlike properties and are collectively known as polyhydroxyalkanoates (PHAs). Many organisms can use PHAs as an energy source by employing secreted de-polymerases to break down the polymer into water-soluble monomers. Many different co-polymers are produced by a variety of organisms, but the homopolymer poly(β -hydroxybutyrate), PHB, is the most common type of PHA. In *R. eutropha* bacteria, three genes are involved in the biosynthesis of PHB, *phbA* encoding β -ketothiolase, *phbB* encoding the NADPH-dependent acetoacetyl-CoA reductase,

and *phbC* encoding PHA synthase. Significant PHB production in leaves of transgenic *Ara-bidopsis* (14% dry weight) was first demonstrated by Nawrath *et al.* (1994). This was achieved by introducing all three bacterial genes into the plastid via the N-terminal addition of the small subunit RUBISCO-targeting peptide. However, *B. napus* oilseed may provide a better system for PHB production because acetyl-CoA, the substrate required in the first step of PHB biosynthesis, is prevalent during fatty acid biosynthesis. For this reason, Houmiel *et al.* (1999) introduced all the three genes into *B. napus* and PHB accumulated in leucoplasts to levels of as high as 7.7% fresh seed weight of mature seeds. The researchers cloned all the three bacterial genes into one binary vector as three modular cassettes, each consisted of the *L. fendleri* oleate 12-hydroxylase promoter, an open reading frame encoding a chloroplast transit peptide fused to the open reading frame of one of the bacterial genes, and the 3' termination region of the *Pisum sativum rbcSE9* gene. The construct was introduced into *B. napus* using *Agrobacterium*-mediated transformation. The group also made the efforts to produce PHBV co-polymer (Slater *et al.*, 1999), which is structurally more flexible than PHB because of reduced crystallinity and is suitable for many commercial applications. The synthesis pathways for PHB and PHBV are essentially identical, differing only in the initial metabolites. Synthesis of PHB is initiated by the condensation of two acetyl-CoA molecules, whereas PHBV synthesis requires the additional condensation of acetyl-CoA with propionyl-CoA. Since the concentration of free propionyl CoA in plants is low, it was necessary to include a fourth gene, *IlvA* from *Escherichia coli*, to redirect intermediates of metabolism to provide a pool for PHV biosynthesis. PHBV co-polymers were accumulated in *B. napus* seeds but only at levels less than 3% of seed weight, which is considerably lower than the calculated economically viable level of 15% polymer in the seed (Houmiel *et al.*, 1999).

2.1.8 Pollination control systems

The topic is comprehensively reviewed by Nasrallah (2004). Heterosis (hybrid vigor) has been observed in canola hybrids (Starmer *et al.*,

1998). The heterotic effect is variable and depends on the parental lines used for hybrid seed production. Both *B. napus* and *B. rapa* oilseed cultivars are largely autogamous and are capable of undergoing both self-pollination and cross-pollination, therefore a pollination control system is required for hybrid seed production. Although SI and CMS exist as pollination control systems for commercial hybrid seed production, these are not always stable and may not be available in the desired germplasm. A number of pollination control systems using transgene approaches have been documented (Perez-Prat and van Lookeren Campagne, 2002). In *B. napus*, male sterility was obtained through expression of the cytotoxic gene *barnase*, a ribonuclease (RNase) gene from *Bacillus amyloliquefaciens*, specifically in the tapetal cells of anthers, thus disrupting normal pollen development (Mariani *et al.*, 1990; Denis *et al.*, 1993). The tapetum-specific expression is achieved by using the TA29 promoter isolated from tobacco. The TA29::*barnase* gene was linked to the herbicide resistance gene *bar*, allowing selection against male-fertile herbicide-sensitive progenies by herbicide treatment shortly after germination. Male sterility was restored by expressing an RNase inhibitor gene *barstar* in the tapetum. Expression of *barstar* in the tapetum has no effect on tapetal development, and plants expressing this protein are male fertile (Mariani *et al.*, 1992). This is a very elegant pollination control system and has been shown to function satisfactorily in the field for the commercial production of hybrids in oilseed rape without adverse effect on the agronomic performance of the crop. A persistent problem in hybrid breeding schemes based on nuclear or CMS is inefficient pollination of male-sterile plants. Male-sterile flowers are less attractive to honey bees than male-fertile flowers because they lack pollen and secrete only one-tenth the amount of nectar produced by male-fertile flowers, and they can also have reduced number or size of nectarines (Pernal and Currie, 1998).

Until recently, attempts to transfer the SI trait into autogamous species by a transgenic approach were not successful (Bi *et al.*, 2000). However, the structural analyses of the Brassica *S* locus regions (Cui *et al.*, 1999; Brugiere *et al.*, 2000), and the identification of the male and female determinants of SI specificity (Schopfer *et al.*,

1999; Cui *et al.*, 2000; Takasaki *et al.*, 2000) have made this approach a feasible strategy for hybrid breeding. Some haplotypes of the Brassica *S* locus is physically short and could be easily transferred as single transgene in one transformation event using the BIBAC vector (Cui *et al.*, 1999, 2000; Brugiere *et al.*, 2000), thus it is possible to transfer the genomic region covering the entire *S* haplotype into a self-fertile elite line of *B. napus*. Similarly, the male and female SI gene pair isolated from one *S* locus haplotype can also be transferred into one plant to introduce the SI trait into elite self-fertile canola lines. The *S* haplotypes may be linked to a selectable marker such as an herbicide resistance gene, allowing for relatively straightforward single-cross hybrid production (Nasrallah, 2004).

2.2 Transformation Strategies

Genetic transformation procedures have been successfully developed for all oilseed Brassicas, but by far more work has been done with *B. napus* than with any other species. Particularly, the spring canola line “Westar” has been widely used in the past. Most of these methods require an efficient plant regeneration system from either single cells or complex tissues.

The most widely used gene transfer technique in oilseed Brassica is *A. tumefaciens*-mediated transformation because it is compatible with a number of *Brassica* species, genotypes, and explants (Dale and Irwin, 1994; Dale and Irwin, 1995; Walden and Wingender, 1995; Damgaard *et al.*, 1997; Poulsen, 1996). The wild type bacterium causes the formation of crown gall tumors on infected plants by inserting DNA containing genes for synthesis of auxin and cytokinin (T-DNA from the bacterial Ti plasmid) into plant chromosomes. Disarming the T-DNA by removing the hormone genes, together with introduction of reporter genes, selectable markers, and genes of interest, has converted *A. tumefaciens* into an excellent system for genetic transformation. Explants are co-cultivated with the bacteria for a brief period (usually several days) and then cultured under conditions that kill the bacteria and allow the growth and regeneration of transformed cells. Various explants have been used for regeneration, e.g., stem internodes (Fry *et al.*, 1987), stem

segments (Pua *et al.*, 1987), cotyledonary petioles (Moloney *et al.*, 1989), hypocotyls segments (Radke *et al.*, 1988; De block *et al.*, 1989; Stewart *et al.*, 1996; Cardoza and Stewart, 2003), microspores (Jones-Villeneuve *et al.*, 1995; Souvire *et al.*, 1996; Fukuoka *et al.*, 1998; Nehlin *et al.*, 2000), and protoplasts (Herve *et al.*, 1993). However, hypocotyls remain the most commonly used explants for transformation and have been used in most transformation experiments. The virulence of *Agrobacterium* can be enhanced by using a phenolic compound called acetosyringone and it is now being used routinely in canola transformation (Halfhill *et al.*, 2001; Cardoza and Stewart, 2003). The transformation efficiency can be improved by preconditioning of the explant on callus inducing media before co-cultivation (Radke *et al.*, 1988; Ovesna *et al.*, 1993; Schroder *et al.*, 1994; Cardoza and Stewart, 2003). The co-cultivation period is also critical and a period of 2 days was found to be optimal (Cardoza and Stewart, 2003).

In planta transformation has been developed and used most extensively in the model plant *A. thaliana* (Clough and Bent, 1998). The method does not require tissue culture and plant regeneration and the procedure is simple. It includes a brief dipping of flowers in *A. tumefaciens* cultures, allowing seeds to set. Subsequently, seeds are harvested and transgenic seedlings selected. Recently, Wang *et al.* (2003b) demonstrated that a similar dipping procedure can be adopted to produce transgenic *B. napus* plants. The published current transformation efficiency is low (up to 0.018%), but once it is optimized the method is expected to have major impact on how transgenic Brassicas are produced. The advantages of *in planta* transformation are obvious, including circumventing the genotype dependence, the labor and facilities needed for tissue culture, and the ease and speed to produce transgenic plants.

Agrobacterium rhizogenes are sometimes an alternative biological vector for gene transfer and relatively high transformation efficiencies have been documented (Boulter *et al.*, 1990; Damgaard and Rasmussen 1991; Spak *et al.*, 1991; Dusbabkova *et al.*, 1993; Zaccomer *et al.*, 1993). Explants incubated with wild-type *A. rhizogenes* can integrate and express T-DNA from its Ri plasmid, leading to the formation of hairy roots. Such roots can serve as a

starting point for recovery of transformed plants, via spontaneous or hormone-induced plant regeneration from transformed hairy root cultures (Christey, 1997). Regenerated plants from such cultures share some general characteristics such as abundant formation of plagiotropic roots, wrinkled leaves, shortened internodes, reduced apical dominance, and later flowering (Tepfer *et al.*, 1989). It was demonstrated that *A. rhizogenes* strains are effective in transforming *Brassica* species by co-transformation of both the Ri plasmid and the binary vector (Boulter *et al.*, 1990; Christey and Sinclair, 1992). Plants regenerated from transgenic hairy roots show a relatively wide range of Ri phenotypes due to different expression levels of the *rol* loci of the Ri plasmid, but some normal plants carrying the gene of interest can later be obtained in progeny since the two T-DNAs may be integrated into different chromosomes and segregate (Boulter *et al.*, 1990).

Particle bombardment (biolistics, gene gun) is a widely used alternative method for direct DNA delivery for species that are not readily amenable to *Agrobacterium* infection. It has been successfully used in the generation of transgenic plants from cultured and isolated Brassica microspores (Chen and Beversdof, 1994; Fukuoka *et al.*, 1998). The method is attractive for its high efficiency compared to that of *Agrobacterium*, but there is a tendency for multiple copy insertions and potential instability of the transgenics.

Microinjection is another possible way for direct transfer of DNA. There has been only one successful report using this method. Transgenic plants were obtained when DNA was injected into the nucleus of 12-cell microspore-derived embryos (Neuhaus *et al.*, 1987); but not when uninucleate microspores were used as targets (Jones-Villeneuve *et al.*, 1995). The method, however, is potentially useful because of the precision of DNA delivery and the ability to select the targets for injection.

All the transformation methods described above for oilseed Brassicas are used for targeting the transgenes into the plant nuclear genome. This means the transgenes could be transmitted to the progeny and related weedy species through pollination, an environmental concern. Recently, a method has been developed for chloroplast transformation in *B. napus*, where the transgenes were integrated into the chloroplastic rather than

nuclear genome (Hou *et al.*, 2003). The authors inserted genes for antibiotics resistance gene and insect tolerance into a chloroplast transformation vector and introduced into cotyledon petioles by bombardment. Transgenic plants were subsequently obtained, which demonstrated insect tolerance, as expected. The plastid transformation offers at least two advantages over the nuclear transformation. First, the chloroplast traits are maternally inherited and can not be transmitted to genetically related species by pollination and thus preventing the transgene flow to related species. Second, high copy numbers of transgenes means increased transgene expression.

2.3 Selection of Transformed Tissue

For most transformation methods, only a small number of cells are infected with the introduced DNA and the majority of the cell populations do not contain the gene of interest. To give these transformed cells a selective advantage for growth and organ differentiation, it is necessary to screen them at an early stage after infection. To this end, some selectable markers are incorporated into the construct along with the genes of interest. Antibiotic resistance genes are commonly used, such as neomycin phosphotransferase (NPTII) gene from Tn5, which confers resistance to kanamycin and other aminoglycoside antibiotics neomycin, gentamycin, and also paromomycin. Another effective selection marker for Brassica transformation is *hygromycin phosphotransferase (hpt)* from *E. coli* providing resistance to hygromycin (van den Elzen *et al.*, 1985). Aminoglycoside-3-adenyltransferase (*aadA*), the gene responsible for resistance to spectinomycin and streptomycin, is also a suitable selection marker for *B. napus* (Schroder *et al.*, 1994). The herbicide-resistance gene *bar*, which confers resistance to both bialaphos- and D+L-phosphinothricin is frequently used as selectable marker (de Block *et al.*, 1989). Among the selection markers used in oilseed Brassicas, kanamycin is the predominant marker. There is, however, evidence that it limits regeneration in brassicas (Thomzik and Hain, 1990; Gupta *et al.*, 1993).

A positive selection employing the enzyme phosphomannose isomerase, which allows transformed cells to use mannose as carbon source, has been applied successfully to Brassica oilseed

transformation (Bojsen *et al.*, 1994). The selection is based on the fact that most plants are unable to metabolize mannose or mannose-6-phosphate and introduction of the phosphomannose isomerase gene that converts mannose-6-phosphate into fructose-6-phosphate facilitates the growth and selection of transformed cells and plants.

To address the concerns over the use of these marker genes, primarily from an ecological perspective, such as the possible transfer of antibiotic and herbicide resistance genes from transgenic plants to pathogenic bacteria or related weedy species, strategies to produce marker-free transgenic crops have been developed in the recent years, based on genetic segregation and site-specific DNA deletion systems (Puchta, 2003). Marker-free *B. napus* transgenic plants have been generated by using co-transformation (Daley *et al.*, 1998). Plants were transformed with a single *A. tumefaciens* strain containing two binary plasmids, each of which carried either NPTII or the reporter GUS gene. Approximately 50% of the primary transgenic plants were shown to express both the transgenes. Progeny expressing only one of the transgenes were observed in about 50% of the co-transformed lines, indicating that the genes were inserted at different loci.

2.4 Regeneration of Whole Plants

Plant regeneration occurs mainly through organogenesis for most explants but somatic embryogenesis occurs in a number of cases (Pua, 1990; Graves *et al.*, 1991). There are a number of factors that affect the efficiency of organogenesis, such as source and age of the explants, genotype, ethylene inhibitors, and media constituents. Although organogenesis at high frequency can be achieved from various explants, hypocotyl segments remain the most desirable explants for tissue culture and have been used for most *Brassica* species. A survey of 70 articles on transgenic oilseed Brassicas conducted by Pua and Lim (2004) shows that 85% employed hypocotyls and cotyledons from less than 2-week-old seedlings for the study of transformation, while only 15% used stem segments from the older plants. In seedlings, the majority of studies (72%) used explants of less than 1-week-old. The survey also shows the preference of hypocotyls (82%) over cotyledonary explants

(18%). Most researchers have found that explants excised from 3–4-day-old seedlings gave optimal regeneration rates.

Regeneration of Brassicas is highly genotype dependent. Ono *et al.* (1994) surveyed 100 *B. napus* cultivars for their ability of shoot regeneration from cotyledonary explants. A huge variation was found, ranging from 0% to as high as 99%, under the optimal explant age and plant growth regulators. Phogat *et al.* (2000) also found that the *B. napus* cultivar GSL-1 has better regeneration efficiency than Westar. Thus, genotype dependency is a limiting factor in Brassica tissue culture and regeneration and consequently transformation efficiency, which can only be overcome by *in planta* transformation strategy (Wang *et al.*, 2003b).

Ethylene inhibitors, such as aminoethoxyvinylglycine or silver nitrate, supplemented to the medium has been shown to be beneficial to regeneration of *B. campestris* (Radke *et al.*, 1992; Kuvshinov *et al.*, 1999), *B. napus* (Halfhill *et al.*, 2001; Cardoza and Stewart, 2003), and *B. juncea* (Pua and Lee, 1995; Mehra *et al.*, 2000; Prasad *et al.*, 2000). The inclusion of ethylene inhibitors is intended to inhibit the synthesis and action of ethylene that has long been found to be accumulated in cultured plant cells and tissues (La Rue and Gamborg, 1971), and cause abnormal plant growth and development (Lentini *et al.*, 1988) and also possibly affect shoot organogenesis (Pua and Gong, 2004). In addition, there are possibly many other media supplements that might increase regeneration efficiencies. For example, methylglyoxal-bis-(guanylhdyrazone), an inhibitor of spermidine biosynthesis, was reported in two studies to significantly increase regeneration frequencies (Sethi *et al.*, 1990; O'Neill *et al.*, 1996).

Somatic embryogenesis in Brassica crops is relatively lagging compared to other plant species, likely due to the advanced organogenesis techniques developed in Brassica. However, there have been a few reports on somatic embryos obtained from hypocotyls (Kohlenbach *et al.*, 1982), protoplast-derived colonies (Kranz, 1988), and immature cotyledons (Turgut *et al.*, 1998) in *B. napus*. Somatic embryogenesis has also been reported in rapid-cycling *B. napus* hypocotyl explants using MS basal medium with low pH (3.5–5) (Koh and Loh, 2000).

2.5 Testing of Transgenic Lines

Putative transgenic plants obtained after *in vitro* selection and plant regeneration need to be assayed to confirm whether the introduced gene(s) is stably integrated into the host genome and efficiently expressed. There are several standard methods commonly used to verify transgene integration and expression. Putative transgenic plants can be assayed for a selectable marker enzyme system, such as neomycin phosphotransferase or phosphinothricin acetyl transferase activity in the extracts of transgenic tissues (Reiss *et al.*, 1984; McDonnell *et al.*, 1987; Radke *et al.*, 1988). The presence of these enzymes can also be detected using antibody-based assays such ELISA and immunoblot analysis (Girich *et al.*, 1995). The *E. coli* β -glucuronidase (*uidA*) gene is very often included in the transgene construct and used as a reporter of the transformation event. The expressed β -glucuronidase activity, GUS, can be easily assayed qualitatively by histological staining or quantitatively by spectrophotometric measurement of the activity in plant extracts (Jefferson *et al.*, 1986, 1987). It is also used in promoter analysis for examining the gene expression pattern. Since early 1990s, polymerase chain reaction (PCR) has become a quick way to amplify the integrated transgenes. However, the well-established DNA blot and RNA blot analyses remain as definitive assays for transgene integration, copy number, and expression level.

Once confirmed transformants are identified, the transgene inheritance stability and segregation can be analyzed in the selfed progeny of primary transformants. The segregation data not only demonstrate whether the transgene is inheritable and efficiently expressed, but is also a good estimation of the copy number of active transgene insertion loci. The stability of gene expression in transgenics is a fundamental issue for commercial acceptance. Gene silencing and inactivation occur frequently in transgenics and in some instances may not be evident for several generations (Kumpatla *et al.*, 1997). This phenomenon exists in transgenic oilseeds but not to the extent observed in other species; there are very few reports for *Brassica* species (Blakemore *et al.*, 1995; Jones *et al.*, 1995; Metz *et al.*, 1997; Conner *et al.*, 1997). It is generally accepted that transgene

inactivation is related to gene copy number and the sequence similarity between the transgenes and endogenous genes (Finnegan and McElroy, 1996). Indeed, by using a *SRK* allele that has less sequence identity and a weaker native promoter; Takasaki *et al.* (2000) were able to circumvent the co-suppression problem and successfully expressed the *S*-locus receptor kinase gene *SRK* in *B. rapa*. There are other strategies reportedly helpful to minimize transgene silencing (Kasschau and Carrington, 1998; Vain *et al.*, 1999), but their efficacy in *Brassica* species remains to be proved.

The concept of “substantial equivalence” is currently used by all jurisdictions as a first step in evaluating whether a transgenic crop is safe for production and consumption (Kuiper *et al.*, 2001, 2002). That means that transgenic plants must have no negative attributes and be the same as its nontransgenic progenitor except for the engineered trait. Therefore, the transgenic plants need to be thoroughly analyzed, before commercial release, for pleiotropic effects that are unrelated to the intended primary trait of interest. Such unintended pleiotropic effects have been documented for transgenic oilseed Brassicas. Knutzon *et al.* (1992) developed a transgenic rapeseed line with enhanced levels of saturated fatty acid, stearic acid, in its seed oil. Later analysis revealed that the stearic acid was not only present in the storage oil as expected but also “leaked” into the membrane lipids of the developing seeds. The tiny amount of leaked stearic acid is expected to reduce membrane fluidity and lead to functional defects. Indeed, the stearate-rich seeds tended to have relatively poor germination rates (Thompson and Li, 1997). In another example, changes in chemical composition of plant tissues as a result of unrelated genetic manipulation were observed. Abidi *et al.* (1999) analyzed oil derived from different lines of transgenic canola for phospholipids, tocopherols, and phytosterols. Besides the changes in phospholipids, they also found variations in the concentration of tocopherols and phytosterol composition. These unintended pleiotropic effects were all found by analyses of certain limited target traits.

Approaches to monitor/assess the global changes caused by the insertion of transgenes have been developed in the model plant *Arabidopsis*. Similar strategies could soon be potentially

applied to transgenic oilseed crops, given the international efforts devoted to the Brassica genomics (www.brassica.info) and the fact that they belong to the same plant family and are thus genetically closely related. Recently, El-Ouakfaoui and Miki (2005) conducted a microarray analysis to search for transcriptome changes in *Arabidopsis* with strong expression of transgenes (*nptII* and *uiaA*) regulated by constitutive promoters using the *ATH1 Arabidopsis* GeneChip from Affymetrix. Their data implies very little functional disturbance to the genomes of transgenic plants by the insertion of simple T-DNA constructs, i.e., transgenic plants generated with simple T-DNA constructs containing common marker genes are fundamentally equivalent to nontransgenic plants. Similarly and conceivably, metabolomics (Keurentjes *et al.*, 2006), proteomics (Peck, 2005), and ionomics (Salt, 2004) technologies developed in *Arabidopsis* could also applied to assess the issue “substantial equivalence” of transgenic crops. However, substantial equivalence is a starting point in the safety evaluation, rather than an endpoint of the assessment, which may include immunological, toxicological, and biochemical testing (Kuiper *et al.*, 2001, 2002).

2.6 Regulatory Measures

Regulations of transgenic plants vary greatly from country to country.

2.7 Canada

In Canada, all four herbicide-resistant types of *B. napus* are regulated identically as “plants with novel traits (PNTs).” The Canadian Food Inspection Agency (CFIA) defines PNTs as “plant varieties/genotypes that are not considered substantially equivalent, in terms of their specific use and safety both for environment and for human health, to plants of the same species in Canada, having regard to weediness potential, gene flow, plant pest potential, impact on nontarget organisms, impact in biodiversity, antinutritional factors, and nutritional composition. PNTs may be produced by conventional breeding, mutagenesis, or more commonly by recombinant DNA techniques” (www.inspection.gc.ca/english/sci/biotech/reg).

2.8 United States

The use of crops produced via biotechnology is regulated by three US government agencies. Their responsibilities are complementary, and in some cases overlapping. The USDA Animal and Plant Health Inspection Service (APHIS) regulates field testing of biotechnology-derived plant varieties (www.aphis.usda.gov). The US Environmental Protection Agency (EPA) is the lead agency for evaluating crop plants with pesticidal traits developed via biotechnology. The US Food and Drug Administration (FDA) Center for Veterinary Medicine is the primary agency regulating the safety of livestock feeds developed via biotechnology. The federal government of the United States of America has a co-ordinated, risk-based system to ensure new biotechnology products are safe for the environment and human and animal health (<http://usbiotechreg.nbio.gov>). Established as a formal policy in 1986, the Coordinated Framework for Regulation of Biotechnology describes the Federal system for evaluating products developed using modern biotechnology. The Coordinated Framework is based upon health and safety laws developed to address specific product classes. A searchable database is available (http://usbiotechreg.nbio.gov/Search_pub.asp) that covers genetically engineered crop plants intended for food or feed that have completed all recommended or required reviews for food, feed, or planting use in the United States. Included in the database are a number of canola transgenic lines that were engineered for a variety of traits, such as herbicide tolerance, phytate degradation, altered fatty acid and oils, and male fertility.

2.9 Australia

There are currently no commercial transgenic canola crops grown in Australia. The Office of Gene Technology Regulator (OGTR) oversees gene technology research in Australia (www.ogtr.gov.au). OGTR has set out guidelines and advice on how GM organisms can be handled. An Institutional Biosafety Committee (IBC) must be set up for each transgenic type. The IBC ensures that OGTR guidelines and advice are followed for that particular type. The 1998 requirements for field trials in Australia were that the trial must be

400 m from any other Brassica crop, the trial area including the buffer and a 50 m area surrounding the trial must be kept free of Brassica and related weeds, a 15 m canola buffer is to be planted around the trial as a pollen trap, and canola can not be sown on the trial area for three seasons after the trial.

3. FUTURE ROADMAP

The advent of genomics opened many new doors for the biotechnology improvement of Brassica crops. The volume of expressed sequence tag (EST) collections in the public domain (GenBank) has been increasing drastically over the last few years. In parallel, proteomics and metabolomics data sets are being generated from various stage of development. A multinational consortium of *B. rapa* genome sequencing is also currently underway, and the full genome sequence information is expected to be available in the coming years. Such resources will serve as a foundation for an integrated understanding of genome composition, gene expression profile, post-transcriptional regulation of gene products, and interaction of the metabolic network, all of which are important for biotechnology improvement of plant performance and crop productivity.

An emerging trend in Brassica biotechnology is the appreciation of complementarities between traditional breeding efforts employing classic genetics and molecular biology approaches predominated by target gene identification. Many of the agronomic traits are governed by genetic components that exert quantitative control. Aided by the availability of breeding populations developed through DH technology first established several decades ago (Keller *et al.*, 1975, 1977), genetic linkage analyses aimed at fine mapping of QTL in Brassica have been plentiful (Liu *et al.*, 2006). Identification of specific genes corresponding to the QTLs, however, remains a major obstacle. The last few years have witnessed many successes in the combined application of genomic tools with genetic linkage analysis to identify QTLs in *Arabidopsis* (Keurentjes *et al.*, 2006). Similar research is now expanding to crop species. Research in Brassicaceae has the unique advantage of extensive genome synteny between

Brassica crops and *Arabidopsis* (Parkin *et al.*, 2005). In practice, what this would mean is that many of the QTLs relevant to agronomic traits can be aligned to specific regions in the *Arabidopsis* genome within which a guided and focused search can be conducted to identify the corresponding genes. Furthermore, the voluminous EST database enables the development of comprehensive gene chips in Brassica, which will be available from several sources in the near future. This would allow mapping of hundreds of expression QTL (eQTL) and integrated mining of combined genetic linkage and expression experiments (Clarke and Zhu, 2006).

Improvement of seed yield remains a top priority in Brassica biotechnology. Such a need is further accentuated by the potential of seed oil as a renewable resource for biodiesel. While biofuel can only contribute to the overall energy scheme as a supplement to the petroleum industry in the foreseeable future, the superior efficiency of seed oil in energy conversion (Hill *et al.*, 2006), and its unique property as lubricant in enhancing engine fuel efficiency, can not be ignored. Nonetheless, in comparison to cellulose, considered a major bioenergy solution, a constraining factor of seed oil based biofuel is the limited biomass crops produce. With extensive efforts on study of QTL genes concerning yield, delineation of primary genomic control points that can serve as genetic modification targets will pave the road for future endeavors in this direction. Enhancing oil content through modifying lipid metabolism offers a matching opportunity to seed yield, and there have been reported successes under green house conditions in this regard (Jacko *et al.*, 2001). TFs that control seed oil deposition in *Arabidopsis* have also been identified (Cernac and Benning, 2004). Utility of transgenic alteration of such genes is expected to enhance oil yield in Brassica crops. Despite of these progresses, there is still a pressing need for extensive field trial experiments to assess the potential of these technologies under variable environmental conditions. Recently, a major breakthrough in understanding carbon flux control in developing seed of Brassica revealed a new pathway that employs Rubisco without the Calvin cycle to increase the efficiency of carbon use during the formation of seed oil (Schwender *et al.*, 2004). Better understanding of this pathway, known as the "Rubisco bypass", promises to

provide insight into the regulation of storage lipid biosynthesis and has obvious ramifications for improving seed oil content.

A variety of metabolites possessing either positive or negative health effects exist in Brassica. As a major source of vegetable and edible oil for human consumption, Brassica crops have been the subjects of extensive efforts in biotechnology improvement of nutritional value. Carotenoids and vitamin E contents in oil have been the major targets for quite some time (Shewmaker *et al.*, 1999; Ravanello *et al.*, 2003; Kumar *et al.*, 2005). Such a trend will likely to continue. Phytosterol, a significant component in seed oil with well-established effects in lowering the risk of cholesterol and cardiovascular associated diseases (Ostlund, 2002), has attracted considerable research efforts. In recent years, Brassica seed meal as a source of animal feed has also been explored. Phytate, glucosinolate, flavonoids, anthocyanins, and proanthocyanidins metabolism are all being targeted for improvement of meal quality. Studies in a broad spectrum of genes encoding enzymes of various biochemical pathways have generated mounting evidence suggesting that metabolic regulation is often distributed in, not one, but multiple steps of metabolic pathways. Thus, increasingly, transgenic efforts are gearing toward introduction of multiple genes, commonly referred to as "stacking" strategy, in order to achieve maximum effects in metabolic pathway engineering. Such a strategy generally requires several individual gene expression cassettes, each one of them would demand a separated promoter to drive a tissue-specific gene expression. Since identical promoters introduced into the same genome contour usually lead to co-suppression during the subsequent generations of the transgenic plants, identifying promoters differing in sequence content but similar in tissue specificity are desirable for the purpose of performing multiple gene transformation.

A research area crucially important for the agricultural production of Brassica crops worldwide is to improve crop efficiency in soil nutrient utilization, particularly with regard to nitrogen (N) and phosphorus (P) (Raghothama and Karthikeyan, 2005). N and P are predominant nutrient factors limiting plant productivity. Applications of N and P fertilizers bring major economic burdens to farmers in developing countries, and modern

agricultural reliance on fertilizer is also believed to have had negative impact to the environment, particularly on ground water quality and aquatic ecosystems. Unlike other major crops, Brassica species do not establish symbiotic interactions with microrhiza. Therefore, improvement of nutrient utilization would have to be focused solely on the plants. There has been major progress in understanding plant responses at the metabolic and gene expression level (Wu *et al.*, 2003). Various advancements in transgenic improvement of P acquisition have also been reported. But there is a need for continued search for novel approaches of genetic engineering for not only nutrient uptake but also efficient utilization.

Release of transgenic Brassica crops has been scrutinized intensively as it should be for a technology that has such a broad relevance to our daily life. The debate continues. A contentious issue particularly concerning transgenic Brassica crops is the separation of food crops from the ones destined for industrial usage (Miller, 2003). As outlined in other sections of this chapter, *Brassica* species are increasingly viewed as an amendable and productive host for producing industrial feedstocks. Indeed, high erucic Brassica cultivars generated through traditional breeding efforts have been cultivated in the Canadian prairies for quite some time (Scarth *et al.*, 1991). However, any real or perceived risk of gene flow from transgenic industrial crops to canola industry as a whole. Fortunately, in addition to *B. napus*, *B. juncea*, *B. carinata*, and *B. rapa* that are traditional crops, there are also other species such as *C. abyssinica* and *Camelina sativa*, which are genetically and metabolically closely related to oilseed crops. Within this context, it can not be overemphasized that future efforts are in urgent need to develop these species into platform hosts for genetic engineering of industrial crops.

1. INTRODUCTION

Cultivated sunflower (*Helianthus annuus* L.) is the only significant agricultural commodity with a North American center of origin. There are two primary types of cultivated sunflower: oilseed sunflower and confectionary sunflower. Oilseed sunflower represents the largest cultivated area of the two and boasts seed oil content in excess of 40%. Most of the seed from this type is crushed to extract its valuable oil that has uses in both food and industrial applications. Oilseed sunflower is also sold as birdseed and is used to some extent to augment feed rations in the poultry, dairy, and beef industry.

Oilseed sunflower is one of the most important oilseed crops in the world and is the preferred source of oil for domestic consumption and cooking in much of central and eastern Europe. Sunflower oil is stable at high temperatures, has a neutral taste, contains less than 11% total saturated fat and does not contain any trans fat. A recent study conducted at Harvard University indicates that consuming sunflower oil in the diet helps to reduce the level of “bad” cholesterol (low-density lipoprotein, LDL) and increases the level of “good” cholesterol (high-density lipoprotein, HDL) while reducing total cholesterol levels in the body (<http://www.sunflowernsa.com>). These characteristics make sunflower oil the preferred oil for health conscious consumers. In an effort to improve the quality and healthfulness of its

products, Frito Lay, the largest salted snack manufacturer in the world, recently announced that by 2007 only sunflower oil will be used in the manufacture of Lays and Ruffles brand potato chips as well as a host of other core snack offerings (<http://www.sunflowernsa.com>).

Confectionary sunflower produces large seeds with low oil content (less than 20%) that are sold as a salted snack in the shell and consumed like peanuts or de-hulled and used in bread or other baking and snack applications. Salted confectionary sunflower seeds have grown in popularity in the United States as celebrity baseball players help to associate the snack with the popular sport. In the last several years, salted confectionary sunflower seeds have become as common at baseball games as hot dogs and cracker jacks.

The inexpensive production of biodiesel from renewable plant vegetable oils such as sunflower oil has been achieved. The demand for biodiesel is increasing rapidly. Furthermore, sunflower can produce high quality rubber in its leaves and stems. The various usages of sunflower products in food, feed, and industry are stimulating the development of sunflower molecular breeding in combination with conventional and transgenic breeding methods. This chapter describes the history of sunflower as an oil seed crop, summarizes the achievements of conventional and transgenic breeding, and discusses the impact of new technologies on sunflower product development.

1.1 History, Origin, and Distribution

Sunflowers of the genus *Helianthus* comprise 49 species native to the Americas that are widely distributed from Mexico to Canada and all of which are found in the United States (Seiler and Rieseberg, 1997). Sunflower has a long history as an important domesticated plant in North America. Much evidence suggests that monocephalic (single headed) sunflower biotypes were cultivated by prehistoric native North American people and may have been domesticated even before corn (*Zea mays*) (Seiler and Rieseberg, 1997). Carbon-14 dating has provided evidence that sunflower was cultivated in the Missouri–Mississippi basin over 2800 years ago (Lees, 1965). After Europeans colonized North America there were many references to the cultivation of sunflower by native people. Heiser (1951a, b) has excellently reviewed this subject.

It is assumed that domesticated sunflower was introduced into Europe by Spanish explorers to the new world. The earliest record is of sunflower seed from New Mexico obtained by a Spanish expedition in 1510 (Zukovsky, 1950). The herbalist Dodoneus made the first published description of sunflower in 1568 describing single-headed forms in Spain that appeared much like the modern cultivars of today. Sunflower spread from Spain into Italy and France where it was used as an ornamental plant in gardens. By the late 16th century it was growing in gardens in Belgium, the Netherlands, Switzerland, Germany, and England (Heiser, 1951a, b; Semelcczi-Kovacs, 1975). As sunflower became widely grown as a garden ornamental in Europe, people began eating the seeds. The custom of eating seeds drove the selection of biotypes with large single heads and large seeds, and promoted the development of landrace cultivars during the late 16th and early 17th centuries.

The first record of extracting oil from sunflower seeds is an English patent (No. 408) that was granted to Arthur Bunyan in 1716. The patent references the use of oil in industrial applications such as the manufacture of paint and wool products. Peter the Great is credited with introducing sunflower into Russia in the 18th century (Zukovsky, 1950) with seed brought from the Netherlands (Semelcczi-Kovacs, 1975). Initially, it was cultivated as an ornamental but by 1779,

sunflower was being cultivated for oil extraction (Gundaev, 1971). By 1830, the extraction of sunflower oil began on a commercial scale in Russia (Atkinson *et al.*, 1919; Quesenberry *et al.*, 1921; Clydesdale and Hart, 1948).

By 1854, cultivation of sunflower for oil had expanded significantly and in the region of Voronzeth, 84 small mills were producing some 2000 tons of oil per year. By 1880, the crop had introduced into Ukraine and in Russia, there were 150 000 ha of sunflower in production (Semelcczi-Kovacs, 1975). By 1915, the area under production in Russia had grown to 0.9 million ha and consisted of two principal varieties: a thin hulled oil type containing between 20% and 30% oil and a large-seeded, thick-hulled variety with low oil content that was grown for direct human consumption (Severin, 1935).

Russian peasants began selecting local cultivars in home gardens with earlier maturities than the original introductions that required long growing seasons and were restricted to warmer environments (Gundaev, 1971). By 1925, breeding programs had commenced at several agricultural institutes, the most important being the institute at Krasnodar where V.S. Pustovit succeeded in raising yield and oil content such that by 1965, he was testing varieties with 55% oil. In other European countries, the adoption of sunflower as a major oilseed paralleled that of Russia. By 1900, sunflower was the primary oilseed crop in Hungary and was being exported to western Europe and the United States (Semelcczi-Kovacs, 1975). France was exporting oil cake to Britain in the middle 1800s. In Romania there were over 320 000 ha of production by 1948 and in Bulgaria, sunflower production had grown to 156 000 ha by 1936 (Semelcczi-Kovacs, 1975). In the Ukraine, production currently exceeds 2 million ha.

Sunflower was reintroduced to North America late in the 19th century with high-yielding Russian cultivars. Two seed companies were offering the variety “Mammoth Russian” by 1880 (Heiser, 1976). It is likely that Russian immigrants brought their favorite cultivars to North America even before this time. While sunflower was an important oilseed in Europe, it was first cultivated in North America as a high-yielding silage crop that was comparable in nutritive value to corn (Wiley, 1901). In the early 1900s, the states with the largest

sunflower production were Missouri, Illinois, and California (Hensley, 1924; Sievers, 1940).

Between 1930 and 1940, the Canadian government requested the Canadian Department of Agriculture to examine sunflower as a potential oilseed crop to reduce Canada's dependency on foreign sources of edible oil (Putt, 1997). Tall, late maturing silage cultivars like Mammoth Russian were not adapted to Canada's short growing season and earlier cultivars that were amenable to mechanical harvest were needed if the crop were to be viable (Putt, 1997). In 1936, about 400 single sunflower heads that were representative of the cultivars that had been selected for earlier maturity and grown by Mennonites in home gardens were collected from the gardens of three farmers in the community of Rosthern (Putt, 1997). In addition to the Mennonite material, about 20 inbred lines from the Central Experiment Farm in Ottawa and 20 cultivars from Russia were planted in progeny rows to form the first major sunflower-breeding nursery in Canada (Putt, 1997).

Inbreeding and selection for desirable agronomic characteristics such as reduced plant height, early maturity, stalk strength, and high seed yield commenced in 1937 and it was observed that many of the Russian cultivars were uniform. One of these cultivars, "S-490" was of short stature, matured early, and produced small seeds with high oil content. It was increased and licensed as the cultivar "Sunrise" in 1942. At the same time the edible oil supply in Canada was critically restricted because of World War II (Putt, 1997).

After 1943, Mennonite farmers who occupied the Red River valley of Southern Manitoba province grew the cultivar "Sunrise" as a cash crop that was more valuable than oats (*Avena sativa*) and barley (*Hordeum vulgare* L.) and was profitable as corn and wheat (*Triticum aestivum*). By 1949, over 24 000 ha were in production in Manitoba and about 8000 ha were being grown in the Southern Red River Valley in the states of Minnesota and North Dakota in the United States (Putt, 1997).

Putt (1940) recognized that cross-pollination occurred at a frequency up to 78% between cultivars. This observation led to the exploitation of heterosis in sunflower hybrids that outyielded inbred parents by up to 250% and outyielded open-pollinated cultivars by up to 60%. One hybrid called "Advance" was released to the public and was produced by crossing a highly

self-incompatible female line descended from Mennonite cultivars with Sunrise as the male. Unfortunately, when the hybrid was produced on a commercial scale, only about 45% of the seed was a true hybrid thus the full heterotic potential could not be realized (Putt, 1997).

Two significant events occurred that would have a lasting impact on the sunflower industry in North America. The first was the introduction of the early maturing cultivar "Perdovic" that had similar yield but higher oil content than "Advance" and other partial hybrids that relied on natural outcrossing and self-incompatibility for seed production (Putt, 1997). The second event was the discovery of cytoplasmic male sterility and fertility restoration genes by the French breeder Leclercq in 1968 (Enns *et al.*, 1970; Kinman, 1970).

With the advent of a cytoplasmic male sterility and fertility restoration system, commercial production of 100% hybrid seed was possible. This greatly facilitated breeding and allowed producers to realize the full potential of heterosis, dramatically increasing yields. Today, sunflower is grown on every continent where crops are cultivated and is the second largest hybrid crop in area after corn.

1.2 Botanical Description

1.2.1 Taxonomy

Helianthus is a member of the subtribe *Helianthinae* of the family *Asteraceae* (Robinson *et al.*, 1981; Seiler and Rieseberg, 1997). Within *Helianthinae*, *Helianthus* is a member of the *Viguiera* assemblage, which comprises *Viguiera*, a large genus of approximately 160 species, as well as a number of smaller, related genera including *Helianthus*, *Helianthopsis*, *Heliomeris*, *Iostephane*, *Pappobolus*, *Phoebanthus*, *Simsia*, and *Tithonia* (Schilling and Jansen, 1989; Seiler and Rieseberg, 1997). This group of genera are characterized by a base chromosome number of $x = 17$ (Robinson *et al.*, 1981) with an estimated genome size of 2871–3189 Mbp (mega base pair) (Arumuganathan and Earle, 1991), the similar nature of the pappus and pales, production of similar floral chalcone/aurone compounds (Crawford and Stuessy, 1981), and the presence of numerous chloroplast deoxyribonucleic acid

(cpDNA) restriction site mutations (Seiler and Rieseberg, 1997).

The genus *Helianthus* has undergone considerable reorganization since Linnaeus originally described nine species in the genus in 1753 (Seiler and Rieseberg, 1997). Herein is presented a modified version of classification of Schilling and Heiser's that was presented by Seiler and Rieseberg in 1997. Seiler and Rieseberg make three minor modifications to the earlier work by Schilling and Heiser: (1) the sectional name *Atrorubens* is given taxonomic priority replacing the section *Divaricati* E.; (2) *Helianthus exilis* A. Gray is recognized as a species instead of an ecotype of *H. bolanderi* A. Gray; (3) the species name *H. pauciflorus* Nutt. was given priority over *H. rigidus* (Cass.) Desf. (Table 1).

1.2.2 Distribution

There are 49 sunflower species of the genus *Helianthus* and all are native to the Americas (Seiler and Rieseberg, 1997). Some species are rare and endangered and restricted to unique environments while others are widespread throughout North America. The genus *Helianthus* is represented by both perennial and annual species with remarkable diversity and found in a wide range of habitats from newly disturbed areas to tall grass prairie and even climax forests (Seiler and Rieseberg, 1997). For a detailed review of species-specific distribution in North America, see *Sunflower Species of the United States* (Rogers et al., 1982).

Several species have been domesticated as ornamentals including the annual species *H. annuus*, *Helianthus argophyllus*, *Helianthus debilis* Nutt., and the perennial species *Helianthus decapetalus* L., *Helianthus maximiliani* Schrad., and *Helianthus salicifolius* among others (Seiler and Rieseberg, 1997). Two wild sunflower species have the distinction of being the only important food plants that were domesticated during prehistoric times in what is now the United States of America; *H. annuus* L. which gave rise to modern cultivated oilseed and confectionary hybrids and *Helianthus tuberosus* L., a perennial species that is cultivated for its edible tuber (Seiler and Rieseberg, 1997).

Charles Heiser at the Indiana University accomplished early work with the *Helianthus* genome involving collection and interpretation of

^(a)Reproduced from Seiler and Rieseberg (1997) and with permission from the National Sunflower Association

^(b)Annual species, all other species are perennial

morphological and cytological data in a series of classic studies from the 1940s to the 1960s (Heiser, 1947, 1949, 1951a, b, 1954, 1965; Seiler and Rieseberg, 1997). Heiser demonstrated the natural occurrence of several interspecific hybrid derivatives in the genus and postulated that natural hybridization and subsequent interspecific gene exchange via natural introgression led to increased morphological and genetic variation in some species that allowed an expansion of their range and may even have led to the formation of introgressive races tending toward *H. debilis*, *H. argophyllus*, *Helianthus Petiolaris*, and perhaps *Helianthus bolanderi* (Seiler and Rieseberg, 1997).

More recently, molecular genetic studies by Rieseberg and others have largely confirmed several of Heiser's hypotheses regarding the important role of introgressive hybridization in the evolution of the *Helianthus* genus (Rieseberg *et al.*, 1990, 1991; Dorado *et al.*, 1992; Seiler and Rieseberg, 1997). For more detailed review of this subject, see Seiler and Rieseberg (1997), Jan (1997), and Jan *et al.* (1998).

1.3 Economic Importance

1.3.1 Planted area

Sunflower is currently grown in North and South America, Europe, Africa, Asia, and Australia. It is the second most important hybrid crop in the world after corn and provides the primary source of vegetable oil in many countries, especially eastern Europe. Table 2, reproduced with the permission from the National Sunflower Association in the United States, describes cultivated hectares and utilization by region from 2000 to 2005. From the table, it is evident that most sunflower seed is consumed domestically and the European Union is the principal net importer of sunflower seeds.

1.3.2 Uses

Sunflower is grown for several uses including oil for cooking and baking, oil for the manufacture

^(a)Reproduced with permission from the National Sunflower Association

of vitamin E supplements, seeds for snack and baking applications, birdseed, and in some cases as a ration component for the poultry, dairy, and beef industries (Dorrell and Vick, 1997; Lofgren, 1997; Park *et al.*, 1997). Sunflower is also widely used as an ornamental plant in gardens all over the world and is used to beautify public by ways such as railways in Japan. In limited instances, sunflower is also grown as a forage crop. Native Americans used sunflower both as a source of food and as a source of pigment in prehistoric times.

Sunflower oil is produced from oilseed sunflower varieties. Sunflower oil is light in taste and appearance and contains more vitamin E than any other vegetable oil. The oil consists primarily of monounsaturated and polyunsaturated fats with low levels of total saturated fats and no trans fat. Sunflower oil is a liquid at room temperature. It is the preferred choice for cooking in most households in central and eastern Europe but is virtually unknown to consumers in the United States where other oils like canola, corn, and soybean have dominated supermarket shelves for years. Most supermarkets in the United States currently do not offer bottled sunflower oil for sale to consumers.

There are three primary oilseed sunflower classes that are differentiated by their fatty acid profiles: linoleic, mid-oleic, and high oleic sunflower (Dorrell and Vick, 1997). Linoleic sunflower is the traditional and most widely cultivated form of the oilseed types. Its oil is predominantly composed of linoleic acid, which is an ω -6 fatty acid. Linoleic acid is one of two essential fatty acids required for human health that must be consumed in food. Linoleic sunflower oil is composed of about 65% polyunsaturated linoleic acid, 21% monounsaturated oleic acid, and about 11% total saturates (palmitic and stearic fatty acids). Linoleic sunflower oil is the preferred cooking oil in much of central and eastern Europe. Mid-oleic sunflower oil is characterized by oleic acid content between 55% and 75% with the balance comprised of linoleic acid and saturated fatty acids. Mid-oleic sunflower contains less than 10% saturated fat, which is lower than linoleic sunflower oil. Mid-oleic sunflower oil is stable at high frying temperatures without the need for partial hydrogenation, a process that is used to stabilize other oils like soybean oil. The hydrogenation process results in the conversion of

some fatty acids to trans fat, which has recently been found to increase the risk of heart disease in humans. The US Food and Drug Administration (FDA) has stated that no level of trans fat in the diet is safe and recent US legislation requires all food manufacturers to list the amount of trans fat present on food products in the United States.

In the United States, mid oleic sunflower is the preferred oil type for commercial frying applications due to its relatively high oxidative stability, health benefits, and neutral taste profile. Crossing a linoleic inbred line with a high oleic inbred line produces a mid oleic sunflower hybrid. The resulting progeny and harvested seed exceed the 55% oleic acid threshold that defines the mid oleic category. Mid oleic sunflower has been given the trademark NuSunTM by the National Sunflower Association in the United States. NuSunTM sunflower oil has recently been adopted by Frito Lay, the largest salted snack manufacturer in the world, as the sole source of oil utilized in Ruffles, Lays, and several other branded chips and snacks including the Lay's "Natural" line. Like all sunflower oil, NuSunTM contains no trans fat, has significantly lower levels of total saturated fats than conventional hydrogenated oils, and provides desirable frying stability and better taste attributes than alternatives. NuSunTM oil has only been available to manufacturers since 1998 when commercial volumes became available for the first time following efforts by the National Sunflower Association to promote commodity-priced sunflower oil that was stable at frying temperatures and low in saturated fats. Before then, only linoleic and high oleic varieties were grown in the United States (Dorrell and Vick, 1997).

High oleic sunflower boasts an oleic acid content exceeding 80%. High oleic sunflower oil is used both in food and industrial applications including spray coatings for cereals, crackers, and dried fruits and use in nondairy creamers. In Europe, high oleic sunflower oil is blended with linoleic sunflower oil to produce targeted oil profiles for niche market applications or is used directly for specialty uses including the manufacture of baby foods and hydraulic fluids. In the United States, high oleic sunflower oil is used in food and industrial applications (Dorrell and Vick, 1997).

Confectionary sunflower, characterized by its large, thickly hulled seeds are sold as salted

snacks in the shell or are de-hulled for use in baking and snack applications. In China, salted confectionary sunflower is a popular snack and can be found in markets across the country. In the United States, salted confectionary sunflower seeds have grown in popularity and are sold at most major league baseball parks. They are available as traditional salted seeds and recently there has been an explosion of flavored offerings including cool ranch, pickle, and hot chili flavors.

1.4 Traditional Breeding

1.4.1 Breeding objectives

As with other commodity crops, the primary objective for sunflower breeders is to increase the overall yield and agronomic performance of newly developed confectionary, high oleic, linoleic, and NuSunTM hybrids (Fick *et al.*, 1974). To accomplish these goals, breeders need to address pathogens, pests, and environmental constraints that have the potential to drastically reduce yield where sunflowers are grown. Chief among these constraints are diseases including *Sclerotinia* (*Sclerotinia sclerotiorum*), downy mildew (*Plasmopara halstedii*), rust (*Puccinia helianthi*), *Phomopsis* (*Phomopsis helianthi*), *Verticillium* wilt (*Verticillium dahliae*), Charcoal rot (*Macrophomina phaseolina*), and head rot (*Rhizopus* spp.).

Other breeding considerations include increasing resistance to insect pests such as moths (*Homoeosoma nebulellum*, *Homoeosoma electellum*, *Cochylis hospes*, and *Suleima helianthana*), seed weevils (*Smicronyx sordidus*, *Smicronyx fulvus*), sunflower midge (*Contarinia schulzi*), sunflower beetle (*Zygogramma exclamationis*), and wireworms (*Pterohelaeus altenatus*) among others. Breeders also strive to increase inbred yields to lower the cost of hybrid production and develop hybrids with shorter plant height and a range of maturities adapted to a wide range of growing environment. Stalk strength, lodging resistance, drought resistance, and salt tolerance are other breeding targets.

Breeders in some markets including Turkey, Spain, Romania, and the Ukraine must develop genetic resistance to the rapidly evolving parasitic plant broomrape (*Orabanche cummana*) that can completely destroy farmers' fields if resistant

hybrids are not utilized. Recently, breeders have incorporated resistance to imidazolinone (IMI) and Sulfonyleurea herbicides into sunflower hybrids to improve weed control options for farmers. The chemical company BASF labeled the herbicide "Beyond" for use on Imazimox-tolerant hybrids in the United States in 2003. DuPont labeled the Express[®] SX herbicide for use on sunflower hybrids with tolerance to tribenuron-methyl in Romania, Hungary, and Bulgaria in 2005 and will label Express for use on resistant hybrids in the United States in the spring of 2007. Pioneer Hi-Bred International, Inc. was the first seed company to market Express-tolerant sunflower and other companies are expected to enter the market in the near future.

Breeders of oilseed hybrids seek to increase the oil content of new hybrids and breeders of confectionary sunflower seek to improve seed size, de-hulling ability, and seed color characteristics. All of these considerations, including those listed in the section above, must be made while striving to improve the heterotic yield potential of newly developed hybrids.

1.4.2 Tools and strategies

Sunflower has been bred as a hybrid crop for 40 years following Leclercq's discovery of cytoplasmic male sterility and fertility restoration genes (Leclercq, 1969). There are tremendous opportunities for yield gain and improvements in disease and pest resistance through conventional breeding that have not yet been made. Additionally, there are several wild annual and perennial species that outcross readily with cultivated *H. annuus* that provide a rich source of novel yield and disease quantitative trait loci (QTL) that might be exploited through conventional breeding. For a detailed review of species that cross readily with *H. annuus*, see "*Sunflower Species of the United States*" (Rogers *et al.*, 1982).

Sunflower breeders have recognized the value of exotic germplasm from wild species for decades and several publicly funded breeding programs such as Fundulea in Romania, the institute at Krasnodar in Russia, and the United States Department of Agriculture's breeding center in Fargo, North Dakota have had active wild species breeding programs for years. These programs

have fostered the improvement of elite germplasm through the identification and incorporation of disease resistance genes from wild species including genes for downy mildew resistance, rust resistance, and *Sclerotinia* tolerance. Improved germplasm from these institutions has been made available to private seed companies through public releases that can be obtained for a nominal fee.

In 1990, the United States Congress authorized the establishment of a National Genetics Resource Program with responsibility to acquire, characterize, preserve, document, and distribute to scientists germplasm of life forms important to food and agriculture. The United States Department of Agriculture's Agriculture Research Service maintains a web-based Germplasm Resources Information Network (GRIN) that lists available germplasm including exotic sunflower accessions that are available to breeders free of charge. For details about this tremendous resource, see the GRIN website at <http://www.ars-grin.gov>. Currently, there are roughly 3000 accessions of *Helianthus* that are maintained at the North Central Regional Plant Introduction Station in Ames, Iowa.

Since about 1970, sunflower hybrid breeders have developed inbreds from two primary heterotic pools: a male pool and a female pool. The male pool is fixed for fertility restoration genes and is typically fixed for recessive branching genes. Recessive branching in males is a desirable trait that extends the pollen shed of males in hybrid production fields ensuring pollen availability when females are flowering. Fertility restoration genes are necessary to restore fertility to hybrids made with sterile females so that the hybrids can self-pollinate to produce harvestable seed. Males are called restorer lines as they restore fertility to cytoplasmic male-sterile females as described above.

From the female pool, breeders develop two analogous single-headed biotypes: a fertile "maintainer" (B line) and a male sterile (A) line. The maintainer line carries the wild-type cytoplasm rather than the sterile one; it is fertile but does not carry fertility restoration genes for the sterile cytoplasm. The male sterile (A) line carries the sterile cytoplasm, but also lacks restorer genes for that cytoplasm. The sterile (A) line is developed by backcrossing the nuclear genotype of the maintainer into the sterile cytoplasm. When

the maintainer line is crossed onto the male sterile line, the offspring are all sterile. To make commercial hybrid seed, the sterile (A) line is planted in alternating strips with a restorer (male) inbred. The hybrid seed is harvested from the sterile strips. The maintainer is needed to multiply, or "maintain" the A line.

Breeders develop new inbreds within the male pool by crossing elite restorers, and within the female pool by crossing elite maintainers. From a line development standpoint, breeding in the male pool requires less time than breeding in the female pool as newly developed lines can be evaluated in hybrid combinations for yield and other agronomic characteristics as soon as they appear to be genetically and morphologically uniform, typically after 4–6 generations of inbreeding following the initial cross. Female inbred development takes longer as the maintainer line must be developed first, then the sterile (A) line analogue must be developed through backcrossing.

To accelerate new product development, breeders typically employ alternate environments to achieve two or more generations per year. If breeding in the northern hemisphere for example, a breeder may exploit a southern hemisphere environment or a low latitude tropical location during winter months to achieve an additional generation. In India, where temperature is not limiting but where natural moisture constrains the growing environment, sunflower breeders exploit the natural fluctuation of rainy seasons in different geographies to achieve two generations per year.

In cases where breeders have selectable markers for desirable traits like herbicide resistance or disease resistance, backcrossing is employed to convert proven elite lines lacking these traits. This is often accomplished in greenhouses or tropical environments where two or even three generations can be obtained per year. Sunflower floral induction and maturity is influenced by day length and by the accumulation of heat units and the combination of these factors differs widely with genotype. In some cases, a breeding cycle can be shortened by manipulating these parameters in a growth chamber or by growing the material in short-day tropical environments like Hawaii. Another tool that is sometimes employed to shorten cycle time is embryo rescue, where immature embryos are excised and grown in tissue

culture, permitting breeders an opportunity to artificially shorten the time required to recover new progeny.

1.4.3 Breeding with molecular markers

There have been considerable discoveries in the public sector that have facilitated the advancement of molecular breeding in sunflower. The first molecular genetic linkage maps of cultivated sunflower were developed by using restriction fragment length polymorphism (RFLP) markers (Berry *et al.*, 1994, 1995, 1996, 1997, 2003; Gentzbittel *et al.*, 1992, 1995, 1999; Jan *et al.*, 1998) and random amplified polymorphic DNA (RAPD) markers (Rieseberg *et al.*, 1993; Rieseberg, 1998; Yu *et al.*, 2003). Subsequently, several genetic linkage maps were constructed using amplified fragment length polymorphisms (AFLP) markers (Peerbolte and Peleman, 1996; Gedil *et al.*, 2001b). RAPDs have been used for tagging phenotypic loci in sunflower such as rust and broomrape resistance genes (Lawson *et al.*, 1998; Lu *et al.*, 2000b). More recently, simple sequence repeat (SSR) markers have been developed for cultivated sunflower that have provided a dense public reference map that could be used to unify independently developed linkage maps and establish a universal linkage group nomenclature (Gedil, 1999; Tang *et al.*, 2002, 2003a, b; Langar *et al.*, 2003; Mokrani *et al.*, 2003; Yu *et al.*, 2003).

Tang *et al.* (2002) constructed the first genetic linkage map of sunflower based on SSR markers and the first dense public genetic linkage map based on single- or low-copy DNA markers (Yu *et al.*, 2003). The map was developed with recombinant inbred lines (RILs) derived from a cross between a public confectionary restorer line and a public oilseed restorer line (RHA280 × RHA801) both released by the United States Department of Agriculture (USDA) (Fick *et al.*, 1974; Roath *et al.*, 1981; Yu *et al.*, 2003). The map utilized the 1089 SSR markers described by Tang *et al.* (2002) and resulted in 17 linkage groups ($x = 17$) with a total length of 1368.3 cM and a mean density of 3.1 cM per locus (Yu *et al.*, 2003).

Subsequently, Yu *et al.* (2003) published a map that integrated the SSR map of Tang *et al.* (2002) and the RFLP maps of Berry *et al.*

(1997) and Jan *et al.* (1998) and added unmapped markers developed at the Oregon State University, CARTISOL, and Advanta (Yu *et al.*, 2003). Detailed description of this work is available elsewhere (Yu *et al.*, 2003).

The discovery and publication of molecular markers in sunflower has facilitated the implementation of whole genome marker applications that permit breeders to define heterotic groupings of inbred lines and allow the exploitation of these groupings in new breeding crosses and untested hybrid combinations. The availability of dense genetic maps has also facilitated the ability of researchers to make marker-trait associations with important disease resistance and other genes and develop high throughput markers that facilitate marker-assisted selection (MAS) for resistant individuals in segregating breeding populations. Finally, the ability to fingerprint inbred lines with SSR markers permits breeders to employ marker-assisted backcrossing that enables a more rapid and thorough recovery of recurrent parent alleles in trait integration and elite line conversion programs.

The future of sunflower breeding holds enormous promise. Given the power of molecular breeding tools and the vast diversity of wild species and novel alleles therein, the combination and exploitation of these resources in tandem should allow breeders to identify and incorporate valuable traits into elite populations faster than ever before. The rising cost of petroleum coupled with the increasing demand for vegetable oil used in the production of biodiesel and the desire for healthier oils by consumers should increase demand for sunflower oil significantly in the years to come. This, in turn, should increase funding in the public and private sectors for the development of improved sunflower hybrids with better yields and agronomic performance and accelerate the rate of genetic gain for the crop overall.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

With the diversity of germplasm available to breeders and the recent development of molecular breeding tools, it is probable that rapid and significant improvements will be made to sunflower germplasm through conventional breeding

that should dramatically improve yield and the profitability of the crop to growers in the next few decades. These trends should stimulate investments in conventional breeding and transgenic breeding alike. Sunflower genomic researchers are discovering more and more new genes that are associated with various phenotypes. With more markers being developed, MAS will become an increasingly important tool in conventional breeding. However, the lack of genetic diversity for certain traits such as *Sclerotinia* resistance in elite sunflower germplasm could limit the improvements through conventional breeding. Other limitations including the complex and time-consuming process of breeding quantitative traits controlled by multiple genes might be overcome through the identification of simpler single gene systems in other organisms and transfer of these genes into sunflower with the tools of biotechnology.

Transgenic breeding has clearly demonstrated its ability to make significant improvements to agriculture. One needs look no further than a corn or soybean field in the United States to find the considerable improvements that have been achieved using transgenics. The major advantage of transgenic breeding over conventional breeding is the vast potential for incorporating desirable traits without the limitations of reproductive barriers between species, or linkage drag that is often problematic with breeding efforts involving wild species. Transgenic breeding is complementary to conventional breeding. The combination of the two breeding approaches has enormous potential to advance the development of new sunflower products.

The center of origin for sunflower is in North America and concerns have been raised in the United States about the potential for transgenic introductions to outcross with related wild species (Snow *et al.*, 2003). These concerns, coupled with a backlash against transgenic food crops in Europe have increased the cost of transgenic deregulation in most countries due to the demand for detailed environmental impact and human health studies prior to approval by the regulatory bodies that govern food safety. In the seed industry, sunflower generates less revenue than crops like corn and soybean. With the high cost of gaining regulatory approval for new transgenic traits, the focus is on crops like corn and soybeans, where high value traits have greater value capture potential than

in sunflower. This presents a major challenge for sunflower industry. As discussed in Section 3, new technology has the potential to solve the gene flow issue associated with transgenic sunflower. The increase in demand for sunflower that is expected as biodiesel and latex production emerge as viable concerns will likely promote increased funding to sunflower research, including research in transgenic breeding.

2. TRANSGENIC TRAIT DEVELOPMENT

To develop transgenic traits in sunflower, plant biotechnologists require a gene encoding a trait, a promoter that directs expression of the gene, and a terminator for stopping the expression of the gene in a delivery and expression vector. Then a transformation method is employed to deliver and integrate the transgene unit into the sunflower genome. Finally the gene activity and the engineered trait are evaluated in the transgenic plants under various laboratory, greenhouse, and field conditions. In this section, we will elaborate the discovery of genes, promoters, and terminators, the methods of transformation, and the development of new agronomic input traits and output quality traits in transgenic sunflower plants.

2.1 Gene, Promoter, and Terminator Discovery

2.1.1 Genes

As indicated in (Table 3), a number of new trait genes have been isolated and characterized in sunflower in the last decade. These genes have a great potential to be used for engineering various traits in sunflower and other crops. For example, the sunflower albumin gene (*SFA8*) can be used to increase methionine content in sunflower and other crop seeds (Wang *et al.*, 2001; Godfree *et al.*, 2004). New technologies have significantly accelerated trait gene discovery in sunflower. For example, genomic approaches have lead to the discovery of several disease defensive genes from sunflower (Hu *et al.*, 2003). Many genes have been isolated from sunflower using degenerate oligodeoxynucleotides deduced from

the conserved protein domains of plant genes by polymerase chain reaction (PCR). The sunflower homeodomain gene (Gonzalez *et al.*, 1997) and the nucleotide-binding site-leucine-rich repeat (NBS-LRR) type of disease resistance genes (Bidney *et al.*, 2003; Plocik *et al.*, 2004) are good examples. On the other hand, genes from other organisms can also be used to engineer sunflower. Examples include the wheat oxalate oxidase gene (*OxO*), which confers significant enhanced resistance to *Sclerotinia* in transgenic sunflower (Hu *et al.*, 2003), and genes from the bacterium *Bacillus thuringiensis* (*Bt*) that confer insect resistance in sunflower (Pozzi *et al.*, 2000).

Sunflower genome projects are accelerating sunflower gene discovery. Expressed sequence tag (EST) database is continually increasing in size and

is publicly available. Kozik *et al.* (2003) reported that more than 40 000 sunflower ESTs from multiple complementary DNA (cDNA) libraries have been assembled using the CAP3 program and organized into the Composite Genome Project database (<http://cgpdb.ucdavis.edu/>). This assembly represents 12 000 sunflower unigenes. A total of 12 886 EST sequences were released in July of 2003, and these sequences are available through GnpSeq module sequence databases (<http://genoplante-info.infobiogen.fr>). In a genomic study of sunflower embryogenesis, Tamborindeguy *et al.* (2004) reported 1502 unigenes from sunflower protoplasts, while Fernandez *et al.* (2003) identified a number of organ-specific cDNA clones using subtractive hybridization methods. Ben *et al.* (2005) developed

expressing profiling tools in their embryogenesis research and identified several thousands of sunflower EST clones that are associated with embryogenesis. Characterization of these ESTs including functional genomic research and EST mapping will link more and more genes with phenotypes or traits and facilitate conventional and transgenic breeding efforts. These gene discoveries will also promote identification and isolation of more tightly regulated promoters.

2.1.2 Promoters and terminators

A promoter is the 5'-flanking region of a gene. Promoters serve very important roles in transgene expression and determine the expression level and expression pattern of genes and their responsiveness to certain environmental signals. Constitutive promoters (Humara *et al.*, 1999; Schenk *et al.*, 1999; Lu *et al.*, 2000; Gago *et al.*, 2002; Bowen *et al.*, 2003), tissue-specific promoters (Domon and Steinmetz, 1994; Nunberg *et al.*, 1994, 1995; Carranco *et al.*, 1999; Prieto-Dapena *et al.*, 1999; Rousselin *et al.*, 2002; Almoguera *et al.*, 2002a; Baltz *et al.*, 2002), and inducible promoters (Avsian-Kretchmer *et al.*, 2004; Dezar *et al.*, 2005b) are available. As more sunflower genes are characterized, more and more promoters will be available for transgenic breeding approaches. Promoters from other crops may be useful in sunflower and sunflower promoters can be used in other crops as well. Synthetic promoters are also useful. For example, UCP3 (the enhancer of maize Ubi1 promoter is fused to the 5' end of the Rsyn7 core promoter) and SCP1 (the enhancer of cauliflower mosaic virus 35 S (CaMV 35S)) promoters are fused to the 5' end of the Rsyn7 core promoter express strong constitutive activities

in sunflower (Lu *et al.*, 2000; Bowen *et al.*, 2003). These results suggest that desirable promoters can be developed using *cis*-acting elements for engineering-specific traits in plants.

A transcription terminator is a nucleotide sequence that acts as a signal for termination of transcription. The nopaline synthase (Nos) terminator from *Agrobacterium tumefaciens* (Bevan, 1984) and terminator sequence from *Solanum tuberosum* proteinase inhibitor II (PinII) (An *et al.*, 1989) as well as CaMV 35S terminator are the most commonly used terminators in transgenic sunflower plants (Table 4).

2.2 Transformation

2.2.1 Tissue culture and regeneration

The development of a transgenic sunflower requires fertile whole plant transformation. Sunflower plants can be regenerated from somatic and zygotic embryos, hypocotyls, mature cotyledons, and protoplasts. The regeneration rate of whole transformed plants depends largely on genotype, explant type, developmental stage, the culture media, and the growing conditions employed (Bidney and Scelonge, 1997). Genetic elements are closely associated with regeneration ability (Deglene *et al.*, 1997; Flores Berrios *et al.*, 2000). High oleic sunflower genotypes can be rapidly and efficiently regenerated (Mohamed *et al.*, 2003). Jambhulkar (1995) developed a rapid embryo-raised plant system for sunflower production from immature embryos. Fiore *et al.* (1997) developed a high frequency regeneration method via somatic embryogenesis has been used with several sunflower genotypes. The embryogenic

frequency of this method can be as high as 72% and the rooting frequency is up to 82%. The somatic embryos could develop into normal plants and produce viable seeds. Shin *et al.* (2000) successfully regenerated plants from the embryo meristem and primordial leaf tissues of 17 different sunflower genotypes. Sujatha and Prabakaran (2001) found that Gamborg basal salt media induced embryogenesis of immature zygotic embryos. Ozyigit *et al.* (2002) could directly regenerate plants from hypocotyls with a high frequency (29–40%). Efficient protocols have also been developed for plant regeneration from leaves (Yordanov *et al.*, 2002) and split embryonic axes (Hewezi *et al.*, 2003). *Agrobacterium rhizogenes* can induce rooting of *in vitro* regenerated shoots and may improve the rooting rate (Devi and Rani, 2002). These results are useful for the improvement of sunflower transformation and gene transfer systems.

A significant bottleneck to sunflower transformation is low transformation efficiency. Optimizing tissue culture and regeneration conditions is fundamental to increasing overall transformation efficiency. There are several transformation methods that can generate transgenic sunflower plants. Herein are presented the four most common and important methods involving *Agrobacterium*, particle bombardment, protoplast, and chloroplast transformations.

2.2.2 *Agrobacterium*-mediated stable transformation

Sunflower is naturally susceptible to *A. tumefaciens* infection (Braun, 1941). Therefore, *A. tumefaciens*-mediated transformation is the most efficient method for transforming sunflower. Bidney and Scelongo (1997) and Pugliesi *et al.* (2000) have reviewed this transformation method. The transformation efficiency depends largely on genotype. Ten sunflower genotypes were evaluated for their suitability for *A. tumefaciens*-mediated gene transfer based on detection of β -glucuronidase (GUS) gene expression. Transformation efficiencies ranged from 0% to 82.7% GUS-positive plants among the tested genotypes, with hybrid genotypes showing higher transformation rates than inbred lines (Gurel and Kazan, 1999). Stable transformation of sunflower can be achieved using nonmeristematic hypocotyls from inbred

line HA300B with 0.1% transformation efficiency (Muller *et al.*, 2001). Hewezi *et al.* (2002) reported a method for genetically transforming recalcitrant split embryonic axes of immature sunflower (*H. annuus* L. var. RHA266). A simple and reproducible *A. tumefaciens*-mediated transformation system was reported by Rao and Rohini (1999). This method produced up to 2% transgenic fertile plants.

Wounding explants by particle bombardment before inoculating meristems with *Agrobacterium* has been shown to dramatically increase transformation frequency (Bidney *et al.*, 1992). Macerating enzymes (0.1% Cellulase R10 and 0.05% Pectinase) treatment can also improve *Agrobacterium*-mediated transformation efficiency (Weber *et al.*, 2002). An endogenous auxin pulse is among the first signals leading to the induction of somatic embryogenesis (Thomas *et al.*, 2002). Transient expression of a gene encoding isopentenyl transferase, involved in the *de novo* synthesis of cytokinins, significantly increases the recovery of *Agrobacterium*-mediated transgenic shoots (Molinier *et al.*, 2002). Modification of the culture conditions, such as the balance of growth regulators, may also increase the transformation efficiency.

Mohamed *et al.* (2004) reported on the optimization of two parameters affecting transfer DNA (T-DNA) delivery and plant regeneration for two high oleic sunflower genotypes subjected to *Agrobacterium*-mediated transformation. The transformation was performed using strain LBA4404 for Capella and strain GV3101 for the inbred lines. Preculturing the explants for 3 days on SIM2 medium before the bacterial inoculation followed by co-cultivation for 72 h increased the percentage of the transgene expression up to 40% in Capella and SWSR2. It also improved overall regeneration. Ikeda *et al.* (2005) reported that small and branching sunflower varieties can be easily transformed and are useful for molecular genetic research.

Matsumura *et al.* (2005) developed a sunflower transformation system using *A. rhizogenes* strain R1000 harboring *rol* genes in four different sunflower varieties. This protocol includes three steps: gene introduction, shoot and plant regeneration, and seed production. They successfully introduced GUS into the sunflower variety Pacino with this method.

2.2.3 Particle bombardment

Bidney (1990) first reported the successful transfer of a transgene into sunflower by particle bombardment. However, the sunflower plants were only partially transformed. Particle bombardment is an important transformation tool that has been used successfully in several plant species. This method is especially important for dicotyledonous plants like sunflower and soybean. The particle bombardment method involves coating DNA onto microparticles such as tungsten or gold and delivering the particles into target cells with acceleration provided by gun-power or high-pressure gas (Hansen and Wright, 1999). The method can be used to transform sunflower (Lucas *et al.*, 2000); however, particle delivery systems have a limited ability to focus bombardment on target cells. A stainless steel focusing device, which fits to the DuPont/BioRad PDS1000/He particle gun apparatus, was developed for solving this problem (Vischi *et al.*, 1999). This device significantly increases the transformation frequency of sunflower cotyledons. More detail information on transformation using particle bombardment can be found in book chapters (Bidney and Scelonge, 1997; Pugliesi *et al.*, 2000).

2.2.4 Protoplast transformation

Methods for isolating protoplasts from sunflower tissues have been established and there are a number of reports on direct gene transfer into protoplasts (Bidney and Scelonge, 1997; Pugliesi *et al.*, 2000). Sunflower protoplasts can take up antibodies (Briere *et al.*, 2004), suggesting that protoplasts might be used as a tool for studying protein and gene function in transgenic research. Binsfeld *et al.* (2000) obtained asymmetric somatic hybrid plants by polyethylene glycol-mediated mass fusion of protoplasts from perennial *Helianthus* species and hypocotyl protoplasts of *H. annuus*. These results indicate that micronuclear induction and asymmetric somatic hybridization can facilitate the transfer of genes into economically important sunflower lines. Plasmid DNA delivery into protoplasts may be achieved with ease. Regeneration from sunflower protoplasts is possible, but the frequency is very low. The challenge with this method lies in the

generation of fertile whole sunflower plants from the transformed protoplasts.

2.2.5 Chloroplast transformation

Chloroplast genomes are maternally inherited and provide a high level of expression with low levels of gene silencing and transgene positional effects. Therefore, chloroplast genomes have been becoming an attractive target for genetic modification and protocols have been developed in some crops (Daniell *et al.*, 2004). Unintended transgene flow via pollen dissemination is a critical issue with genetically modified sunflower plants. Chloroplast transformation is thus of particular interest as a potential means of preventing gene flow from transgenic plants to conventional sunflower or related wild species in field environments. Unfortunately, there is currently no report of sunflower chloroplast transformation. Further efforts are required for more research in this important area for sunflower transgenic breeding.

2.2.6 Selection of transformed tissue

Selection of transformed plant tissues and whole explants are important steps in the development of transgenic sunflower. To facilitate the selection process, selectable markers that can be utilized to identify successfully transformed cells are employed in the process of whole plant regeneration. Genes that confer resistance to selection agents that inhibit growth or kill nontransgenic cells are employed as part of the transformation vector. Bacterial genes encoding resistance to antibiotics or herbicides are commonly used to this end. For example, the *Escherichia coli* *NPTII* gene encodes neomycin phosphotransferase that effectively inactivates kanamycin or neomycin. Kanamycin kills plant cells by inhibiting protein translation. Therefore, in the presence of kanamycin, transgenic sunflower tissues expressing the *NPTII* gene will survive, but nontransgenic cells lacking *NPTII* will be destroyed. Similarly, the *Bar* gene from the bacterium *streptomyces hygroscopicus* encodes phosphinothricin acetyl transferase (PAT) can also be used as a selection marker. PAT converts

the herbicide phosphinothricin into its nontoxic acetylated form and allows growth of transformed plants cells expressing the *Bar* gene in the presence of phosphinothricin. Other commercial glufosinate ammonium-based herbicides such as BASTA™ or Bialaphos can be used for selecting *Bar*-transformed sunflower tissues (Goodwin *et al.*, 2004). Enzymatic-mediated colorimetric reactions such as those observed with wheat OXO (Hu *et al.*, 2003) and GUS (Bidney and Scelonge, 1997) have also been used as positive selection markers.

Transgene integration, expression, and localization in plants need to be confirmed at the molecular level. Southern blot analysis and/or PCR assay can be utilized to confirm the presence and copy numbers of transgenes in the genome of transformed sunflowers. Northern blot assay and/or reverse transcription-PCR (RT-PCR) analysis can be employed to confirm the expression level of a transgene at the transcriptional level, and Western blot and/or enzyme-linked immunosorbent assay (ELISA) or enzymatic analysis may be used to confirm expression at the protein level (Ingham, 2004; Liu *et al.*, 2004; Page and Minocha, 2004).

2.3 Transgenic Improved Traits

Crop yield is the most important trait targeted by crop scientists and farmers alike. The ultimate goal of plant biotechnology is to transfer useful genes into elite germplasm for the improvement of the productivity and quality of crops. As the global human population increases, the food supply will need to expand to meet increased demand and to maintain human nutritional health. In an effort to increase crop yield, plant biologists have applied technologies to generate transgenic plants with improved resistances to diseases, insects, and herbicides as well as enhanced tolerance to abiotic stresses. Most of the efforts to improve sunflower seed quality have been focused on oil and amino acid modifications. In the following sections, we present various transgenic approaches for improving input agronomic and output quality traits in sunflower. In addition, we will also address the potential industrial uses of sunflower and its impact on the sunflower transgenic approach.

2.3.1 Disease resistance

Fungal diseases, such as *Sclerotinia*, *Phomopsis*, rust, downy mildew, and *Alternaria* are the most important disease problems for sunflower production worldwide. Two bacterial diseases in sunflower are widespread and caused by *Pseudomonas syringae* pv. *tagetis* and *Xanthomonas campestris* pv. *helianthi*. Virus diseases are relatively less important in sunflower. Conventional breeding programs have targeted improving resistance to sunflower pathogens for decades. For diseases like downy mildew and rust that can be controlled by single dominant resistance genes, breeders have been very successful in identifying new resistance alleles in wild species and integrating them into elite germplasm (Gulya *et al.*, 1997). However, for more complex diseases like *Sclerotinia*, desirable levels of resistance have often been hard to achieve due to the lack of genetic variations, the complexity inherent to multigenic resistance mechanisms, and the lack of consistent and reliable disease screening methods.

Sclerotinia wilt caused by *S. sclerotiorum* (Lib.) de Bay is the most important fungal disease of sunflower. Under the right environmental conditions, it causes sunflower root rot, stem rot, and head rots (Lu, 2003). The annual crop losses caused by this fungal pathogen are in a range of \$50–\$80 million. Transgenic expression of the wheat *OXO* gene shows great promise for enhancing resistance to *Sclerotinia* (Lu *et al.*, 1998, 2000; Scelonge *et al.*, 2000; Hu *et al.*, 2003). The *OXO* gene was originally named as germin and was isolated from a wheat cDNA library (Dratewka-Kos *et al.*, 1989). Genomic DNA clones encoding *OXO* were also isolated from wheat genomic library (Lane *et al.*, 1993). The *OXO* gene used for transforming sunflower was isolated from a wheat line (Pioneer, 2458) and encodes a protein identical to the wheat germin gf2.8 *OXO* (Lane *et al.*, 1991). *OXO*-transgenic sunflower plants have been generated with a vector utilizing the constitutive SCP1 promoter (Lu *et al.*, 2000), the omega prime messenger RNA (mRNA) leader sequence from tobacco mosaic virus (Gallie *et al.*, 1987), and the potato proteinase inhibitor (PINII) 3' terminator (An *et al.*, 1989) in a pBin19 vector (Bevan, 1984), that was transferred through *Agrobacterium*-mediated transformation (Bidney *et al.*, 1992; Lu *et al.*, 2000; Scelonge *et al.*, 2000).

The *OXO* transgene in sunflower is the full-length coding region of *gf2.8* including the signal peptide for protein expression in the intercellular space. *A. tumefaciens* strain EHA105 was used to transform the sunflower line SMF3 in a modified meristem culture method as described previously (Scelonge *et al.*, 2000). The transgenic plants were identified by an *OXO* enzymatic activity assay (Hu *et al.*, 2003) or by *OXO* ELISA analysis (Scelonge *et al.*, 2000). Whole explants were regenerated from the secondary culture of nodal meristems of transformed plant sectors. The T_0 plants are chimeric. Therefore, most of the bioassays were carried out at T_2 or more advanced generation after confirming positive transgene expression at the protein level (Scelonge *et al.*, 2000; Hu *et al.*, 2003).

When *OXO*-transgenic and nontransformed sunflower plants were subjected to infection by *Sclerotinia*, disease-induced lesions in transgenic sunflower leaves were significantly smaller than those in the leaves of nontransformed controls. Lesion sizes in the transgenic leaves were inversely related to the endogenous levels of *OXO* activity (Hu *et al.*, 2003). *Sclerotinia* spread to the head tissue of the control plants, but the lesions on the transgenic plants were primarily confined to the main stem. These results demonstrated that *OXO* can confer significant *Sclerotinia* resistance in transgenic sunflower (Hu *et al.*, 2003). Greenhouse, screenhouse (cage), and small block field bioassays also showed that *OXO*-transgenic lines exhibited significantly enhanced resistance to mid-stalk rot, root rot, and head rot (Lu *et al.*, 1998; Bazzalo *et al.*, 2000; Scelonge *et al.*, 2000). When crossing the transgenic line with natural *Sclerotinia*-tolerant sunflower lines, the hybrids carrying the *OXO* transgene were more resistant to *Sclerotinia* than the corresponding nontransgenic isogenic hybrids. These experiments clearly demonstrate that the combination of *OXO* with natural tolerance genetic background provides a greater level of *Sclerotinia* resistance than that in the currently available commercial hybrids (Bazzalo *et al.*, 2000). The *SCP1* promoter activity and *OXO* activity are stable over generations and preliminary field assays indicated that *OXO* transgenic expression has a little impact on other agronomic traits at proper level of expression.

Enhanced *Sclerotinia* resistance in *OXO*-transgenic sunflower plants is significant and is the first example of a successful transgene-mediated fungal resistance mechanism in plants. However, the *OXO* enzyme has been found to persist in simulated gastric fluid digestion studies, raising concerns about whether the protein may be a human allergen (Jensen-Jarolim *et al.*, 2002). Wheat *OXO* and *Arabidopsis* germinlike proteins have been produced in transformed tobacco plants. *In vitro* and *in vivo* IgE-binding assays with these proteins indicate that wheat *OXO* and *Arabidopsis* germinlike protein are capable of binding IgE via carbohydrate determinants. IgE binding by these proteins is another indicator that *OXO* may have allergenic properties (Jensen-Jarolim *et al.*, 2002).

For transgenic sunflowers, a major concern is the potential for transgene escape from a transgenic crop to wild relatives near production environments (Snow *et al.*, 2003). Burke and Rieseberg (2003) highlighted an important finding concerning the potential escape of *OXO* in *OXO*-transgenic sunflower plants. They backcrossed the *OXO* transgene from *OXO*-sunflowers to wild species. The resulting progeny were grown in containment cages at field sites in Indiana, North Dakota, and California. The *OXO* transgene was shown to enhance resistance to *S. sclerotiorum*, but it did not significantly impact seed production and reproductive fecundity of the wild species. They conclude that it is not the *OXO* gene transfer *per se* that is important, but rather its potential contribution to the relative fitness in related wild species has the potential to influence the persistence of the transgene in the wild (Heritage, 2003). This type of study is important in demonstrating the safety of biotechnology and provides insight to the concern about gene flow to related species. The results from the Burke and Rieseberg study (2003) suggest that genetically enhanced wild plants will not become more “weedy” since they do not produce more seeds than unmodified controls. These results also indicate that the *OXO* transgene would do little more than diffuse neutrally after its escape in the absence of selection pressure for *Sclerotinia* tolerance. Chapman and Burke (2006) further studied the escape of transgenes from crop \times wild hybridization and showed that natural selection, and not the overall rate of gene flow, is the most

important factor governing the spread of favorable transgene alleles.

Two additional enzymes, oxalate decarboxylase (OXDC) and Oxyl CoA-decarboxylase, can convert oxalate to formate and carbon dioxide. These enzymes have been identified and isolated from fungi and bacteria (Hu and Lu, 2005). The fungal *OXDC* gene has been expressed under the control of CaMV 35S promoter in the cytosol and vacuole of transgenic tobacco, tomato, and lettuce plants. Transgenic plants expressing *OXDC* showed remarkable resistance to *Sclerotinia* (Kesarwani *et al.*, 2000; Dias *et al.*, 2006). These plants had a normal phenotype, and the transferred trait was stably inherited in subsequent generations. The bacterial *OXDC* gene could also be used for oxalate degradation and engineering *Sclerotinia* resistance in plants (Dickman and Mitra, 1992). These results imply that *OXDC* would be a useful candidate for sunflower transformation to combat *Sclerotinia* diseases.

Sawahel and Hagran (2006) reported that overexpression of a human lysozyme gene in sunflower can confer *Sclerotinia* resistance. The lysozyme gene was expressed under CaMV 35S promoter and Nos terminator in a binary vector that contain *NPTII* and *GUS* marker genes (Nakajima *et al.*, 1997). The transgenic sunflower plants were generated by *Agrobacterium*-mediated transformation of particle-wounded hypocotyls explants. The transformed shoots were identified by kanamycin selection and GUS assay, and were further confirmed by Southern, Western, and Northern blot analyses. Two transgenic lines, SH-1 and SH-2, highly expressed the lysozyme and were used for *Sclerotinia* infection assay. The leaf infection analyses indicated that overexpression of the lysozyme significantly reduced *Sclerotinia* infection as indicated by fungal colony formation and colony area.

Sunflower biotechnologists have pursued other transgenic strategies to enhance resistance to sunflower diseases. A number of resistance (R) gene homologues have been isolated from sunflower (Table 3), providing a valuable resource for engineering disease resistance in sunflower. Hewezi *et al.* (2006) reported that TIR-NBS-LRR R genes in sunflower and tobacco have a dual role in plant development and fungal resistance. A number of antifungal protein genes

have been identified (Sauerborn *et al.*, 2002; Lu, 2003; Qi *et al.*, 2005). Induced disease resistance and defense pathways have been identified in plants and have potential to control viral, bacterial, and fungal diseases, as well as parasitic weeds in sunflower (Cao *et al.*, 1998; Dmitriev *et al.*, 2003; Hu *et al.*, 2003). Sotchenkov *et al.* (2005) reported that sunflower defensin *SD2* and modified gene homologues showed similar anti-*Fusarium culmorum* activity. Custers *et al.* (2004) reported that sunflower carbohydrate oxidase can produce hydrogen peroxide and confer resistance against bacterial pathogen *Pectobacterium carotovorum* ssp. in transgenic tobacco. In addition, virus-mediated RNAi (RNA interference) technology has great potential to control viral diseases (Moissiard and Voinnet, 2004) in sunflower.

2.3.2 Insect resistance

Over 150 insect species have been reported to infest sunflower. The most damaging insects of cultivated sunflower include the sunflower moth, banded sunflower moth, and sunflower bud moth (Charlet *et al.*, 1987). Little genetic insect resistance has been obtained through conventional breeding. A common strategy for engineering insect resistance in crops is transformation of sunflowers with *Bt* genes that code for insecticidal proteins. *Bt* is a gram-positive soil bacterium that produces a protein toxic to many insect pests in the family Lepidoptera.

Transgenic expression of the *CryIF Bt* gene in sunflower confers significant control of *Rachiplusia mu* and *Spilosoma virginica*, two important insect pests that impact sunflower production in Argentina (Pozzi *et al.*, 2000). The *CryIF* gene was isolated from the Mycogen/Dow AgroScience *Bt* library. The binary vector used for the sunflower transformation included a constitutive promoter SCP1 (Lu *et al.*, 2000), the omega prime leader sequence of tobacco mosaic virus (Gallie *et al.*, 1987), the *CryIF* gene, and the PINII terminator (An *et al.*, 1989). *CryIF*-transgenic sunflower plants were generated from the line SMF3 through *A. tumefaciens*-mediated transformation (Bidney *et al.*, 1992; Scelonge *et al.*, 2000). Whole plants were regenerated from transformed meristem, and the transformed T₀ plants were identified by *CryIF*

ELISA analysis. T₂ generation plants were used for the initial insect bioassay. Bioassay was performed using transgenic leaf discs and *R. mu* and *S. virginica* larvae at seedling and preflowering stages. The feeding assay clearly exhibited enhanced insect resistance of the transgenic leaf tissues compared to the control. Two field bioassays were carried out during the 1999–2000 seasons in Argentina. In these assays, two *CryIF*-transgenic sunflower events exhibited complete resistance to Argentine looper (*R. mu*) infestation at a high level of insect attack (Pozzi *et al.*, 2000).

A *CryIac*-transgenic sunflower line (CMS-PET1) with a plant-optimized *CryIac* gene from *Bt* under a constitutive promoter CaMV 35S and Nos terminator showed insect resistance. The *CryIac* transgene was crossed with *H. annuus* and the progeny showed significant enhanced resistance to Lepidopteran damage. The transgenic × wild sunflower hybrid produced 55% more seeds than the hybrids lacking the *CryIac* gene (Snow *et al.*, 2003). This study confirms the effectiveness of *Bt* genes in controlling insect pests in sunflower, and raises a concern about “gene flow” to wild species that has the potential to enhance the fitness of weeds in the environment. Preliminary analyses suggested that increased seed production may increase the size of wild population (Pilson *et al.*, 2002). These results imply that wild plants could proliferate as weeds with greater fecundity. However, they are different from the conclusion from *OxO*-sunflower studies (Burke and Rieseberg, 2003), indicating gene flow effects on environments depend on the transgene employed.

Jyoti and Brewer (1999) reported that applications of *Bt* can provide resistance to banded sunflower moth (*C. hospes* Walsingham). Along the same line, there are additional potential insecticidal proteins in other bacteria, fungi, or plants (Legaspi *et al.*, 2004). Chang *et al.* (2003) reported that the *H. tuberosus* agglutinin (*HTA*) gene confers resistance to peach–potato aphid (*Myzus persicae*). Efforts of using lectin or proteinase inhibitor genes to engineer sunflower with insect resistance has been reported (Schuler *et al.*, 1989). However, proteinase inhibitors have been shown to have negative impact on the performance of nonruminants such as poultry and swine, and resistances conferred by proteinase inhibitors are not durable.

2.3.3 Herbicide resistance

There are several important weeds that impact sunflower growth and yield. Wild mustard (*Sinapis arvensis*) and broomrape (*Orobancha cumanna*) are examples of two major weeds that impact sunflower production. Weed control is generally achieved through application of herbicides that affect photosynthesis or the biosynthesis of essential compounds in plants. However, crops are often not resistant to the herbicides. Crops that are genetically transformed with herbicide resistance genes give farmers greater flexibility for the control of weeds. Phosphinothricin and glyphosate have been used in transgenic herbicide resistance. These herbicides have effective toxicity to a broad spectrum of weeds, low toxicity to mammals, and a little impact on environmental systems.

The IMI class of herbicides targets the enzyme acetohydroxy acid synthase (AHAS), which is also referred to as acetolactate synthase (ALS). The ALS enzyme governs the first step in the biosynthesis of essential branched chain amino acids. Three *AHAS* genes were cloned from sunflower by Kolkman *et al.* (2004) providing an opportunity to explore the development of transgenic IMI resistance in sunflower.

IMI resistance in sunflower was identified in a wild population of *H. annuus* in Kansas by Miller and Al-Khatib (2002). The basis for IMI resistance in sunflower is the expression of two naturally occurring mutations in the gene that encodes ALS in sunflower and that gives rise to a conformational change in the structure of the ALS enzyme that prevents herbicide binding. IMI resistance has been incorporated into elite germplasm through conventional breeding and is currently sold in the United States, Argentina, and several European countries under the Clearfield™ trademark owned by BASF. Imazimox (labeled as Beyond™) herbicide was approved for use on Clearfield™ sunflowers in 2003. Clearfield™ sunflower hybrids result from a cross between two IMI-tolerant parents. The original releases were derived through extensive backcrossing to commercial sunflower inbred lines in both female and male heterotic pools. The Clearfield™ sunflower system allows growers to control a wide range of grassy and broadleaf weeds. The susceptibility of conventional sunflower to

ALS-inhibiting herbicides coupled with the long soil residual activity of some IMI herbicides can impact crop rotation in sunflower production systems. Sunflower at early developmental stages are more sensitive to ALS-inhibitors than late developmental stages. Therefore, determining the response to soil residual activity of ALS-inhibiting herbicide is important for managing sunflower crop rotations in fields treated with IMI herbicides (Howatt and Endres, 2006).

While resistance to IMI herbicides was incorporated through conventional breeding methods, some have raised concerns regarding gene flow of the IMI-resistance trait to wild species, regardless of the fact that the trait came from wild sunflower in the first place. Massinga *et al.* (2003, 2005) reported on the fitness of imazamox-resistant common sunflower and prairie sunflower. They created hybrids of domesticated sunflower with both common sunflower and prairie sunflower with and without the imazamox-resistance trait, and carried out greenhouse experiments by measuring the growth of IMI-R and IMI-S common and prairie sunflower hybrids under noncompetitive conditions. The relative growth rate, net assimilation rate, leaf area, and total dry weight were similar in IMI-R and IMI-S common and prairie sunflower, whereas plant height of IMI-S hybrid was greater than that of IMI-R common sunflower hybrids. They also did a replacement series study under field conditions in 2001 and 2002 to evaluate the relative competitiveness of IMI-R and IMI-S common and prairie sunflower. They conclude that IMI-R and IMI-S hybrids of both sunflower species were equally competitive. These results indirectly suggest that the ALS mutant genes can be used for engineering sunflower for herbicide resistance and ALS-transgenic sunflower could be expected to have little environmental impact.

Broomrape has become a potential threat to sunflower production in Europe (Melero-Vara *et al.*, 1989) and to alfalfa, peanut, soybean, tobacco, and tomato in North America (Jain and Foy, 1989). Overexpression of a mutant ALS gene in carrot conferred control of broomrape by imazapyr, an ALS inhibitor (Aviv *et al.*, 2002). This mutant *ALS* gene is an interesting candidate for developing transgenic sunflower plants that might permit the control of broomrape in fields treated with IMI herbicides.

However, Clearfield™ sunflower hybrids treated with Beyond™ herbicide in broomrape infested fields in Turkey have not enabled season long control of this aggressive plant parasite. Slavov *et al.* (2005) transformed several tobacco cultivars with a mutant *ALS* gene for resistance to the herbicide chlorsulfuron (Glean®, DuPont). The mutant gene was isolated from mutant *Brassica napus* (Ouellet *et al.*, 1994) and expressed under CaMV 35S promoter and terminator. The binary construct was transformed into tobacco by *Agrobacterium*-mediated transformation following leaf disc method (Horsch *et al.*, 1985). Transgenic plants were identified by kanamycin selection. The efficiency of the herbicide was demonstrated in greenhouse and field trials. An Orobanche/tobacco growth system was used to evaluate the resistance of the transgenic tobacco plants to chlorsulfuron (Glean®, DuPont). These mutant *ALS* or *AHAS* genes are other potential candidates for the development of transgenic sunflower that might be employed for the control of broomrape.

DuPont announced the release of new sunflower hybrids tolerant to Express® SX Herbicide in Europe on May 25, 2006. These hybrids were derived through conventional breeding and permit the use of Express® SX herbicide (Sulfonylurea) for postemergence broadleaf weed control in sunflower production systems. This offering provides farmers with more weed management flexibility and increased levels of weed control versus existing options. Sulfonylureas are a family of herbicides that were discovered by DuPont scientists in 1972 and first commercialized for in-crop use in wheat and barley crops in 1982. The efficiency and economic benefit of Express® SX herbicide has been proven in cereals and now will benefit sunflower growers (http://www.pioneer.mediaroom.com/index.php?s=press_releasesanditem=160).

2.3.4 Tolerance to environmental stresses

With the alteration to global weather patterns that are expected as a result of global warming, more focus has been given recently to the development of transgenic tolerance to abiotic stresses, such as drought, cold, salinity, extreme temperatures, chemical toxicity, and oxidative stress. Drought

and salinity stress tolerance are likely the most important abiotic resistance traits in sunflower. Although transgenic sunflower plants resistant to abiotic stresses have not yet been developed, research on molecular control mechanisms for abiotic stress tolerance has been reported. Liu and Baird (2003) cloned and characterized five drought-regulated cDNAs and 12 salinity-regulated cDNAs from sunflower. Dezar *et al.* (2005a) reported that *Hahb-4*, a sunflower homeobox-leucine zipper gene, is a developmental regulator and confers drought tolerance to *Arabidopsis* plants. *Hahb-4* is regulated at the transcriptional level by water availability and abscisic acid. They overexpressed this gene in *Arabidopsis* under CaMV 35S promoter and Nos terminator. Transformed plants were generated by *A. tumefaciens*-mediated transformation with the floral dip procedure (Clough and Bent, 1998). Transformed plants were selected on the basis of kanamycin resistance and positive PCR assay. The transgenic *Arabidopsis* plants developed shorter stems and internodes, rounder leaves, and more compact inflorescences than the nontransformed controls. Shorter stems and internodes are due to a lower rate of cell elongation rather than changes in the rate of cell division. Transgenic plants were more tolerant to water stress conditions. Under drought condition, the transgenic *Arabidopsis* plants showed improved development, a healthier appearance, and higher survival rates than wild-type plants. These genes and other defense-related genes (Table 3) are exciting candidates for engineering tolerance to environmental stresses through transgenic breeding approaches.

Watanabe *et al.* (2005) introduced a yeast metallothionein gene (*CUP1*) into sunflower and evaluated heavy metal tolerance of transgenic plants at the callus stage taking advantage of the large biomass of sunflower plants. The *CUP1* was isolated from the yeast genome by PCR amplification and expressed in sunflower calli under the CaMV 35S promoter and Nos terminator in an *A. tumefaciens* LBA4404 binary vector. This construct was co-cultured with sunflower calli for 20 min. The transgenic calli were selected based on kanamycin resistance, and further confirmed by PCR and Southern blot analysis. They evaluated the heavy metal (Cd) tolerance of transgenic sunflower calli in terms of 2,3,5-triphenyl-tetrazolium chloride (TTC)-

reducing activity. The TTC method enables one to quantitatively determine the amount of triphenyl formation formed by succinic acid dehydrogenase-mediated TTC-reducing activity. This method was used to select heavy metal-tolerant lines of the transgenic sunflower calli. Several transgenic callus lines showed a high TTC-reducing activity even after treatment with Cd 200 μ m for 10 days. The TTC reducing activity correlates to the expression of *CUP1* gene. These results illustrate the potential for use of transgenic approaches to develop tolerance to abiotic stresses in sunflower.

2.3.5 Modified oil compositions

Sunflower oil is one of the four major sources of edible oil worldwide including soybean (*Glycine max* L. Merr.), sunflower, rapeseed (*Brassica*), and peanut (*Arachis hypogaea* L.). Conventional sunflower oil contains oleic acid (20%), linoleic acid (65%), linolenic acid (less than 1%), and about 12% saturated fatty acid. The main use of sunflower oil is for human consumption. Sunflower oil is very stable against lipid peroxidation and is used for salad dressings, cooking, and frying. Modified oil profiles including high oleic, low linoleic, and even low linolenic fatty acid compositions have been developed successfully through conventional breeding in sunflower (Purdy, 1986; Hammond, 2000). In the United States, traditional linoleic, high oleic, and NuSunTM sunflower oil is available to food processors and to consumers through specialty grocery outlets.

High oleic acid sunflower was originally developed from VNIIMK 8931 by Soldatov (1976) using dimethyl sulfate-mediated mutagenesis. The mutagenized seeds were advanced to M₃ and screened for differing levels of oleic acid. Breeding lines with oleic acid levels as high as 895 g kg⁻¹ were created in 1978. A synthetic population of plants with high levels of oleic acid was obtained in 1982. Plants from this population were selfed to produce the Pervenets lines. A Pervenets female was crossed with the inbred line HA89 to create the first mid oleic or NuSunTM sunflower hybrid (Miller *et al.*, 1987). Genetic studies demonstrated that the mid oleic trait is controlled by at least three genes (Fernandez-Martinez *et al.*, 1989). In a series of field trials conducted in the United States from 1996 to 2000, NuSunTM sunflower

hybrids were shown to have favorable yield and agronomic performance, and they have since been accepted by end users and growers. The adoption of NuSunTM hybrids by growers was so rapid that by 2001 nearly 50% of the oilseed sunflower area in the United States was seeded to NuSunTM hybrids. Further improvements are focused on reducing the level of saturated fatty acids and increasing antioxidant levels in NuSun(tm) oil (Burton *et al.*, 2004). Based on the 2002 US Sunflower Crop Quality Report, NuSunTM mid oleic sunflower oil continue to provide a solution to food processors, food service users, and consumers looking for a cooking oil with excellent taste and performance, and a healthy profile. NuSunTM sunflower oil has excellent oxidative stability without the need for partial hydrogenation. Animal feeding studies conducted by Dr. Robert Bicolost and T. Wilson at the University of Massachusetts indicate that a diet containing NuSunTM sunflower oil can reduce levels of LDL cholesterol without significantly reducing HDL cholesterol. They further demonstrated that consuming mid oleic sunflower oil reduces the risk of cardiovascular disease (Binkoski *et al.*, 2005). The process of developing NuSunTM sunflower oil sheds light on developing transgenic sunflower products with further modifications to the oil profile.

The European Commission supported a project on transgenic nonfood sunflower oil. The aim of the project was to produce plants with high oleic acid content and reduced content of stearic acid as well as plants producing short- and medium-chain fatty acids. Transgenic plants have been produced and introduced into field trials (fifth generation) (<http://www.molecularfarming.com/nonmedical.html>).

The plant oil biosynthesis pathway is well understood (Ohlrogge and Browse, 1995; Voelker and Kinney, 2001). Genes encoding key enzymes involved in fatty acid biosynthesis have been cloned from sunflower and other plants (Voelker and Kinney, 2001; Serrano-Vega *et al.*, 2003). These genes hold promise for exploitation through biotechnology and may permit additional useful oil modifications that could be achieved through targeted alterations of lipid metabolic pathways.

Transgenic sunflower and canola plants that produce high oleic oils have been generated, and the high oleic oil produced by these plants exhibited excellent thermal stability and frying

performance (Dobarganes *et al.*, 1993; Katz, 1997). High stearic oils are targets for delivering trans-fat-free substitutes for hydrogenated oils. New tailor-made (designer) oils are a series of vegetable oils suitable for edible purposes (Sakurai and Pokorny, 2003). High oleic sunflower lines contain relatively high levels of stearic acid (5–6%), which is undesirable in some industrial uses as it elevates the clouding point and adds difficulty to oil processing. δ -9-stearoyl-(acyl carrier protein) desaturase is the key enzyme that converts stearic acid to oleic acid. Oleic acid is generated by specific ACP desaturase. An 18:1-ACP-specific thioesterase then releases oleate for transport to the endoplasmic reticulum (ER) for subsequent triacylglycerol synthesis. A gene encoding δ -9-stearoyl-(acyl carrier protein: ACP) desaturase was cloned from *Ricinus communis* (castor) cDNA library using an Avocado ACP desaturase antibody (Shanklin and Somerville, 1991). Rousselin *et al.* (2002) overexpressed the castor ACP desaturase gene under a sunflower seed-specific promoter Hads10, which comes from the sunflower late embryogenesis abundant gene *hads10*. The Hads10 terminator was used to terminate the transcription of the ACP desaturase transgene in a binary vector. This binary vector was transformed into an interspecific hybrid sunflower line STR by *Agrobacterium*-mediated transformation without additional particle bombardment (Burrus *et al.*, 1996). Transgenic plants were generated by grafting the putative transgenic shoots onto 3-week-old HA300B plants. T₀ plants were selfed and transgenic plants were selected by kanamycin and confirmed by Southern and Northern blot analyses. The transgene was stable from T₁ to T₅. The transgenic plants were evaluated in greenhouse and field over five generations by analyzing the fatty acid compounds of the seed oil. Some transgenic lines showed significant reduction of stearic acid level compared to the nontransformed control plants (Rousselin *et al.*, 2002).

On the other hand, antisense expression of a stearoyl-ACP desaturase gene in sunflower significantly increased saturated fatty acids (Bidney *et al.*, 2002). A sunflower gene encoding stearoyl-ACP desaturase was cloned from sunflower by RT-PCR. The Napin promoter and nopaline synthase (NOS) terminator were used for antisense expression of the *ACP desaturase* gene and the binary vector was transformed into sunflower by

Agrobacterium-mediated transformation (Bidney *et al.*, 1992; Scelonge *et al.*, 2000). The transgenic sunflower lines expressing the antisense stearoyl-ACP desaturase gene increased stearic acid concentrations fourfold in seed and produced over 40% saturated fatty acids. This product has significant industrial uses including coatings, soap, and margarine (Bidney *et al.*, 2002). Antisense technology for increasing saturated fatty acid has also been demonstrated in other crops (Knutzon *et al.*, 1992). Hairpin DNA constructs, containing an intron, can induce posttranscriptional gene silencing (PTGS) with very high frequency in plants. The antisense and PTGS is now commonly called RNAi (Cerutti, 2003). This RNAi technology has been successfully used to modify seed lipids in other oilseed crops (Singh *et al.*, 2000). The new transgenic modified oils show reduced polyunsaturated fatty acids and reduced susceptibility to oxidation. The content of undesirable trans fatty acids in the oil from transgenic plants is approximately one-third lower than that of hydrogenated traditional oils (Singh *et al.*, 2000).

Acyl-ACP thioesterases terminate acyl-chain elongation during fatty acid biosynthesis by hydrolyzing the thioester bond of acyl-ACP (Harwood, 1988). The substrate specificity of ACP thioesterase plays an important role in determining when the acyl chains are cleaved and released from ACPs, thus determining which fatty acids are available for the biosynthesis of storage and membrane lipids in seeds. Serrano-Vega *et al.* (2003, 2005) isolated, cloned, and sequenced a cDNA clone (*HaFatA1*) encoding acyl-ACP thioesterase from sunflower seeds. This gene may be useful for transgenic modification of sunflower lipids.

Fatty acid biosynthesis is a complex process, and the manipulation of a single gene in a pathway may not be enough to obtain the desired oil compositions. Strategies involving gene stacking may be required for achieving desired traits. Kinney *et al.* (2001) summarized and discussed the challenges in the genetic engineering for improving oil quality. The main factors that impact the genetic manipulation efficacy include the fatty acid flux, desaturase gene families, and intracellular transport of desaturase products in plants. There have been success engineering novel fatty acids in transgenic soybean seeds by expressing various

desaturase genes from other plants (Cahoon, 2003; Kinney, 2003). This approach can be used in transgenic sunflower for improving sunflower oil value and producing industrial useful oils for industry.

2.3.6 Amino acids

Sunflower seeds contain significant amounts of storage proteins called helianthinin and 2S albumins. The 2S albumin protein contains 16% methionine and 8% cysteine, and its protein level in sunflower seeds can be as high as 30% of the total albumin fraction (Anisimova *et al.*, 1999). This indicates the 2S gene (designated as *SFA8*) is a good candidate for genetic modification of sunflower and other crop seeds to enhance nutritional qualities. The sulfur-rich amino acids are important limiting factors for ruminant animal nutrition. Feeding ruminant animals with a ration high in sulfur-rich amino acids could increase animal productivity, such as wool growth rates in sheep (Higgins *et al.*, 1989). Transferring the *SFA8* gene encoding sunflower 2S albumin protein into forage plants may permit the development of transgenic forage species that enhance overall ruminant animal health and productivity. For example, the sunflower *SFA8* gene has been used to increase the methionine content in tall fescue (*Festuca arundinacea* Schreb) and *Trifolium subterraneum* subsp. *subterraneum* (Wang *et al.*, 2001; Godfree *et al.*, 2004).

SFA8 was isolated from sunflower by Kortt *et al.* (1991). The amino acid sequence of the purified SFA8 protein was obtained and then screened a sunflower embryo cDNA library using the deduced DNA sequences. To achieve expression in tall fescue, the gene was modified at the C-terminal with the addition of an ER retention signal KDEL. The CAMV 35S promoter was used for constitutive expression in one construct and the wheat cab promoter was used for leaf-specific expression in another expression cassette. The terminator used for both constructs was CaMV 35S terminator. A modified hygromycin (Hm) phosphotransferase gene was used as a selectable marker. Constructs were transferred into tall fescue by particle bombardment. Transgenic cells were selected on Hm (250 mg l⁻¹) and Hm-resistant calli were regenerated into plants.

Western blot analysis indicated that KDEL-target signal significantly enhanced the accumulation of SFA8 protein. The sulfur-rich SFA8 protein accumulated in transgenic plants up to 0.2% of total soluble protein (Wang *et al.*, 2001). The *SFA8* gene was also used to transform *T. subterraneum* subsp. *subterraneum* (Godfree *et al.*, 2004) and lupins (*Lupinus angustifolius* L.) (Molvig *et al.*, 1997). Ravindran *et al.* (2002) evaluated the nutritive value of the transgenic lupin seeds, which contained higher contents of methionine in broiler chickens. The amino acids in transgenic seeds were as digestible as those in conventional lupins. They also evaluated the nutritive value to sheep of transgenic lupin seeds containing the sunflower albumin gene (White *et al.*, 2000). The transgenic lupin seeds contained 2.3-fold higher methionine and 1.3-fold higher cysteine concentrations as compared to wild-type lupin seeds. The transgenic lupin seed increased sheep growth rate by 8% compared to the control. The sulfur concentration of wool and the cysteine concentration of plasma were also higher in the sheep that were fed transgenic lupin seeds. These results demonstrate that *SFA8* can improve the nutritional value of forage crops for ruminant animals like sheep. This is a good example of how sunflower genes may be exploited as valuable resources for improving food and feed value in other plants.

The Commonwealth Scientific and Industrial Research Organization (CSIRO) intends to continue to work toward the commercial release of a line of transgenic subterranean clover with improved nutritional value for enhanced wool growth in sheep. The transgenic clover line expresses the sunflower SFA8 albumin protein that is resistant to breakdown in the rumen of sheep. The selectable marker gene is *NPTII* (neomycin phosphotransferase gene from the bacterium *E. coli*), which confers resistance to the antibiotic kanamycin. The gene expression unit was transferred into clover plants using *Agrobacterium*-mediated transformation (Higgins, 1998). The CSIRO Plant Industry also intended to release a transgenic lupin line expressing SFA8 protein. PAT (from bacterium *s. hygroscopicus*) that confers resistance to the herbicide Basta and GUS were used to select transgenic plants (Higgins, 1997). These transgenic lines exhibited significantly enhanced level of sulfur-amino acid demonstrating their value in animal feed.

While sunflower seed albumin protein (2S or SFA8) shows promise for enhancing the nutritive value of forage crops like clover and lupin, there have been some concerns related to the allergenicity of these proteins. The sunflower SFA8 protein is somewhat homologous to the mature 2S albumin protein of the Brazil nut and shares 34% amino acid residues in common with this allergen. Overexpression of the 2S albumin gene from Brazil nut under the French bean phaseolin promoter and Nos terminator in canola (Altenbach *et al.*, 1992) and sunflower (Scelonge *et al.*, 1993) significantly enhanced the methionine in seed proteins. Kelly *et al.* (2000) examined the potential allergenicity of the sunflower seed 2S albumin protein. Sunflower seed can cause severe anaphylactic reactions in some susceptible individuals. A series of biochemical and molecular analyses demonstrated that several IgE-binding proteins include regions of the high-methionine 2S albumin SFA-8 protein.

2.3.7 Sunflower biodiesel

The biodiesel industry is growing rapidly, and is expected to have a significant impact on vegetable oil production, including sunflower. World consumption of vegetable oils has increased steadily from 62.6 million metric tons (MMT) in 1993 to 87.8 MMT in 2000 (Gobliz, 2002), and demand continues to rise. Demand is being driven by the increased use of edible oils in food preparation and in many industrial products including fuels. *Biodiesel* is a fuel comprised of monoalkyl esters of long chain fatty acids derived from vegetable oils or animal fats. It is a renewable fuel that can be utilized in diesel engines and derived from natural sources of oil like sunflower, canola, or soybean. Biodiesel has much higher density and higher kinematic viscosity than petroleum diesel fuel (Semenov, 2003). A relatively inexpensive and promising method of producing biofuel from renewable plant vegetable oils has been achieved. A mixture of saturated and unsaturated fatty acid methyl esters (ROME) was obtained by esterification of rape oil (Marchenko and Semenov, 1991). High oleic sunflower is particularly attractive for biodiesel since it can produce oil with up to 90% oleic acid, which has high oxidative stability and uniformity. Producing high

concentrations of industrially useful fatty acids in plant seeds has been initiated using biotechnology, and modifications of the fatty acid compositions of vegetable oils can make them more versatile in their uses (Burton *et al.*, 2004). Genes encoding unusual fatty acid biosynthetic enzymes have been isolated from plants. However, the challenge is how to utilize the genes for producing higher concentrations of useful fatty acids in transgenic plants (Jaworski and Cahoon, 2003).

EPOBIO is an international project funded through the European Union's Sixth Framework Programme (FP6) to exploit the economic potential of plant-derived raw materials. One of their projects is to develop sunflower oil for industrial application. Matsumura *et al.* (2005) co-ordinated the research on the production of diesel fuel through ozonation of sunflower oil. To ameliorate some of the negative characteristics of biodiesel fuel including high viscosity, flash point, and pour point, they employed the process of ozonation, which serves in the electroreduction of fatty acid methylesters and breaks long chain fatty acids into shorter molecules. This new method was very effective in improving the viscosity and flash point of sunflower oil, but had no impact on pour point. To increase the economic viability of biodiesel from sunflower, Matsumura *et al.* (2005) have carried out basic research on conversion of waste glycerol to 1,3-propanediol and have been focused on breeding for enhanced oil composition in sunflower seeds. Matsumura *et al.* (2005) point out four issues to be solved in the biodiesel business including price of vegetable oil, a reliable process for continuous production of biodiesel, improving the fuel properties of raw oil, and a technology to convert plant wastes to valuable materials (biorefinery). By comparing various plant oils, they determined that sunflower oil is better suited to biodiesel fuel manufacture than other oils as it is available from mid oleic and high oleic varieties with naturally low levels of saturated fats. Additionally, other parts of the sunflower plant have potential for producing valuable industrial materials. For example, sunflower stems might be used to produce pulp that could be used in paper manufacture. By improving the fuel properties of sunflower through the expression of novel genes from other plants, transgenic breeding has the potential to promote the development of more suitable oils for biodiesel manufacture.

On June 8th of 2006, the European Commission launched the Biofuel Technology Platform and announced the establishment of a Biofuel Task Force within EuropaBio to co-ordinate industry input. Although canola and soybean oils are popularly used in the process of trans esterification, Brazil's new biofuel—H-Bio—is a mixture of cotton, castor bean, sunflower, and soybean oils (BUSINESS LINE, July 02, 2006 Mumbai, July 1, 2006). The biofuel potential of sunflower oil could be a major driver of sunflower biotechnology and transgenic breeding progress in future.

2.3.8 Sunflower rubber

Sunflower is an important global crop that produces latex naturally. It is an ideal plant for producing rubber since sunflower latex is of high quality and some of the taller perennial species have potential for high latex yields. Scientists are attempting to improve the quality and quantity of latex from sunflower plants (Wood, 2002). Rubber manufactured from sunflower latex has the potential to partially replace America's reliance on imported natural rubber and rubber made from petroleum byproducts. Every year, the United States imports million tons of natural rubber at a cost of about 1000 million US dollars (Grow, 2002; Wood, 2002). Most of the natural rubber comes from *Hevea brasiliensis*, more commonly known as the Brazilian rubber tree. Professor John Vederas at the University of Alberta, Canada and his colleagues are working to develop a genetically modified version of sunflower to provide an alternative commercial source of natural rubber. This research was supported by USDA and the National Sciences and Engineering Research Council of Canada (NSERC). Dr. Vederas believes that sunflowers could be genetically modified to produce a reliable source of high quality natural rubber with high quality. The sunflower rubber can be stronger, more resistant to abrasion, less sensitive to cold, and better at heat dispersion than rubber produced from rubber tree latex (Wood, 2002).

The Crop Improvement and Utilization Research of USDA-ARS at Albany, California, has employed sunflower transformation to enhance latex production in sunflower. Their protocol uses both split apices and proximal parts of the cotyledons to incorporate two key genes

in the latex biosynthesis pathway. Herbicide and antibiotic resistance were used for selecting the transgenic plants. Transformants from six experiments were successfully rooted in the greenhouse (USDA-ARS 2005 Annual report). Since transgenic sunflower can cross-pollinate with other cultivated and wild sunflower plants, the group is working on a project designed to evaluate and mitigate the effects of gene flow from transgenic sunflower to wild relatives. The engineering of metabolic pathways in transgenic plants for industrial use has seen exciting progress in the past decade (Capell and Christou, 2004). Transgenic sunflower producing high levels of latex is an important product of this area of research that should be available commercially in future.

2.4 Regulation of Transgenic Sunflower Plants

Biotechnologists, plant breeders, environmental scientists, ecologists, members of society, and government understand that risk assessment procedures are critical for transgenic product development and approval. Processes related to obtaining approval to commercialize transgenic plants are overseen by regulatory authorities operating in different countries under various organizations. All of the transgenic crops that have been commercialized so far have undergone extensive field trials and regulatory studies to determine their stability and safety to humans, animals, and the environment. In the United States, government agencies take primary responsibility for regulating the release of transgenic organisms. Field experiments involving transgenic plants are highly regulated by federal and state laws as well as institutional biosafety committees (IBCs). For greenhouse research with transgenic plants, National Institutes of Health (NIH) has guidelines at four physical containment levels for experiments involving recombinant-DNA molecules (http://www.isb.vt.edu/greenhouse/green_man.section3.htm). These guidelines further categorize experiments according to specific risk criteria and assigns them to one of the four biosafety levels; BL1-P through BL4-P. The purpose of these guidelines is to prevent the transfer of recombinant-DNA from transgenic organisms

in greenhouse experiments to organisms outside the greenhouse. IBCs have been established under the NIH guidelines to provide local review and oversight of nearly all forms of research utilizing recombinant-DNA including transgenic sunflowers. USDA-APHIS (USDA Animal and Plant Health Inspection Service) permits are required for shipping transgenic sunflowers across states, performing greenhouse experiments, and for field evaluations (<http://usbiotechreg.nbii.gov/roles.asp>). All transgenic products require approvals from the EPA (Environmental Protection Agency International Agreements) (<http://www.epa.gov>) and the FDA before commercialization. These approvals require robust data demonstrating that novel transgenic products are safe for human consumption, safe for the environment, and do not negatively impact nontarget organisms. All of the member countries of European Economic Community (EEC) operate under EEC directive 90/220 "on deliberate release into environment of genetically modified organisms." The Organization for Economic Cooperation and Development (OECD) is playing a significant role in coordinating the international harmonization among member countries (OECD, 1986 and 1990), and UNIDO/UNEP/WHO/FAO is contributing to the development and application of common procedures for developing countries (UNIDO, 1991).

In 1992, several governments signed Agenda 21 at the United Nations conference on environment and development in Rio de Janeiro (Taylhardat and Zilinskis, 1992). Part of this agreement commits signatories to fostering the development of an international set of guidelines on safety in biotechnology. Developing countries like China and India are also developing regulatory procedures. In India, the major responsibility for genetically modified organism (GMO) regulation is under the Ministry of Science and Technology and Ministry of Environment and Forests, Government of India (Manjunath, 2005). Two IBC committees and the Review Committee on genetic manipulation are working under the department of Biotechnology (Manjunath, 2005). In China, various regulations have been passed into law by government. One of the agencies responsible for this is the Center for Chinese Agriculture Policy in the Chinese Academy Science (Huang *et al.*, 2002). The assessment of risks to human

health and the environmental risks from the release of genetically modified (GM) plants involves several challenges. Dale *et al.* (1993) described a risk assessment procedure. In sunflower, pollen- and seed-mediated gene flow has already been researched. Field tests have included open-air plots of male-sterile plants and caged plots that containing fertile plants that were pollinated with bees. In some developing countries, sunflower is considered as a minor crop and not much transgenic development work has been done but in other developing countries, some work has been conducted. In the 2000/2001 growing season, there were 0.8 ha transgenic sunflower planted in Chile. However, no further information is available regarding this effort. More information on regulation of transgenic plants is reviewed recently (Lu *et al.*, 2008).

3. FUTURE ROAD MAP

3.1 Expected Products

As discussed in Section 2 and demonstrated in Table 4, both agronomic input and quality output transgenic traits are being pursued in sunflower, but no commercial transgenic varieties are now in the market. *Sclerotinia* is the most destructive fungal disease of sunflower. *OXO* gene conferred significant resistance against *Sclerotinia* in transgenic sunflower (Bazzalo *et al.*, 2000; Lu *et al.*, 2000; Scelonge *et al.*, 2000). However, the *OXO*-sunflowers are not commercialized because *OXO* protein was found to be a potential allergen. Transgenic resistance to leaf herbivory by the Argentina looper was also being explored. Oil modification is another important area for transgenic research in sunflower. Genes encoding sunflower seed albumin have been utilized for transgenic enhancement of sulfur-rich amino acids in other plants for various purposes.

The two primary constraints for transgenic trait development in sunflower are the potential environmental risk of gene flow to related wild species and the cost/benefit relationship of developing and deregulating a novel transgene in the context of its value to stakeholders. Sunflower is open-pollinated and there are in proximity to some 49 related wild species in the United

States. Transgenic sunflower plants can hybridize with plants in naturally occurring wild sunflower populations and transfer the transgene into these populations. This risk is more relevant for input traits including insect resistance, disease resistance, herbicide resistance, and tolerance to abiotic stress. Quality traits, such as oil modification, pose less risk as these traits should have no impact on survival fitness or the fecundity of related weedy species.

Mutation breeding has been a primary driver for the advancement of modified sunflower products with novel traits. High oleic and NuSun™, hybrids with modified oil profiles, Clearfield™, and Express® Herbicide Tolerant Sunflowers are examples of new products on the sunflower market that have exploited mutations for favorable traits and that were developed through conventional breeding methods. These products are not transgenic. The acceptance of these new products by sunflower growers and industry customers alike has the potential to facilitate the acceptance of certain sunflower transgenic traits. Sunflower biodiesel and rubber production are examples with the potential to drive new advances in sunflower biotechnology. New technology like the integration of transgenes into chloroplasts may also stimulate additional investments in sunflower biotechnology by mitigating the risk of gene flow to related species.

Of all of the transgenic initiatives to improve sunflower, transgenic oil modification holds the greatest potential for commercial candidacy. Supporting rationale include the following: first, oil modification genes pose less environmental risk from gene flow to wild populations; second, genes are available for modifying oil composition and increasing oil yield; third, oil is the primary driver for the overall sunflower market; and finally the potential of sunflower oil for industrial applications like biodiesel should foster new investments in research and product development for oil modification and oil yield enhancement in sunflower.

Sunflower oil contains more vitamin E than any other vegetable oil, high levels of monounsaturated and polyunsaturated fats, and low saturated fat levels. This fact determines the health benefit of sunflower oil. Vitamin E consists of two types of compounds: the tocopherols and the tocotrienols.

The α -tocopherol is the most biologically active form of vitamin E. The majority of vitamin E in the diet comes from vegetable oils such as sunflower oil. It functions as an antioxidant nutrient and plays a significant role in protecting the body against damage to cell membranes. Vera-Ruiz *et al.* (2006) mapped a gene that control vitamin E accumulation and scientists at the University of Georgia recently isolated genes for the synthesis of various fatty acids and vitamin E (http://www.csrees.usda.gov/nea/plants/sri/pbpgg_sri_sunfloweroil.html). Their discovery will promote transgenic approaches to develop healthier sunflower oils with longer shelf life and novel vitamin E and industrial useful sunflower oil for biodiesel. Actually, Van Eenennaam *et al.* (2003) reported that overexpression of *Arabidopsis* gene encoding enzymes in the vitamin E synthesis pathway significantly increases the vitamin E level in soybean seeds. These results indicate that high vitamin E sunflower is another promising product in the future sunflower market.

Many trait genes (Table 3) from sunflower and other crops are currently available for transgenic applications to improve crop productivity and quality. The combination of conventional breeding method and transgenic approaches has the potential to drive synergy in sunflower product development. Biotechnology and new molecular technologies hold tremendous potential for improving modern agriculture. Transgenic sunflower varieties with enhanced disease resistance, modified oil profiles, increased grain yield, and improved agronomic performance should therefore be available to growers in the future. Industrial sunflower plants that produce fatty acids for biodiesel production in the seeds and natural rubber in leaves and stems may also be available in the future.

3.2 Risk Assessment

Many objectives of transgenic breeding are the same as those in conventional breeding. The major difference between the two approaches is the expanded gene pool that is available for transgenic research. Genes from unrelated plant species, bacteria, fungi, viruses, and even animals can be transferred into a crop genome

for the expression of favorable traits. For example, *Sclerotinia* resistance can be achieved by inserting a wheat *OXO* gene into the sunflower genome (Lu, 2003), whereas this is not possible through traditional breeding. Introducing novel genes into crops such as sunflower may also pose potential risk. Even in conventional breeding, gene combinations can sometimes give rise to undesirable gene products (Dale *et al.*, 1993). Glucosinolates in *Brassica* species (Thompson and Hughes, 1986) are good examples. Similarly, transgenic insertions may generate undesirable gene combinations with unintended impact on the environment (Chassy *et al.*, 2004).

The development of transgenic crops has been primarily limited to species of high economic importance to the developed world such as maize, soybean, cotton, sunflower, rice, and potato. The relative lack of transgenic research in developing countries is ultimately driven by funding limitations in those countries. One of the advantages of biotechnology is that once a new approach has been developed, it can be applied to other crops. Yield has always been the most important trait target for seed companies and growers. More than 30% of the yield losses experienced in agricultural production systems are due to biotic factors such as predation by insects, diseases, and competition from weeds. Therefore, input traits with the potential to significantly offset yield losses have been the primary focus of biotechnologists to date, and the first four commercialized transgenic crops have been developed for insect or herbicide resistance (Manjunath, 2005).

Sunflower pollen remains viable for several months at room temperature. There are 13 annual species, and cultivated *H. annuus* is an improved form of its wild *H. annuus* counterpart that is a weed in cropping systems. Gene flow from domesticated or transgenic sunflower plants to wild species has been well documented (Daniell, 1999; Faure *et al.*, 2002). For example, the IMI-resistant gene can flow from domestic sunflower to IMI susceptible common sunflower and prairie sunflower (Massinga *et al.*, 2003). A plant ecologist, Allison Snow, and her team studying *Bt* sunflower found preliminary evidence of gene flow from transgenic sunflower to wild plants. This is the major concern and risk for

transgenic sunflower traits. They studied a *Bt* transgene, *cry1Ac*, in backcrossed wild sunflower populations and observed that reduced herbivory allowed transgenic plants to produce an average of 55% more seeds per plant than nontransgenic controls at a field site in Nebraska. A similar but nonsignificant trend was seen at another site in Colorado (14% more seeds per plant). In a greenhouse experiment the transgene had no effect on fecundity, suggesting that it was not associated with a fitness advantage. Snow *et al.* (2003) reported the first experimental evidence indicating that transgenes could move from transgenic crops and introduce novel traits into related species. This potential risk cast a potential shadow over the advancement and realization of biotechnology's full potential in sunflower. However, Burke and Rieseberg (2003) reported that *OXO*-enhanced wild plants did not produce more seeds than the unmodified controls, and that the *OXO* transgene would do little more than diffuse neutrally after its escape. Chapman and Burke (2006) focus on the escape of transgenes from cultivated crops via crop \times wild species hybridization and show that natural selection, and not the overall rate of gene flow, is the most important factor governing the spread of favorable alleles in wild species. Massinga *et al.* (2005) reported that the IMI-resistance gene has little impact on the competitive ability of common and prairie sunflower. In general, the ecological impacts of transgenic sunflower are largely unknown. When addressing the environmental impact of a transgene, the space, time, genetic background, and abiotic stresses need to be taken into account (Chapman and Burke, 2006).

Although greenhouse and field trials have been conducted in the past several years, no transgenic sunflower product has been commercialized to date. Consequently, it is too early to evaluate the impact of transgenic sunflower on humans and the environment. Since the very first transgenic crop was commercialized in 1996, transgenic crops with improved input and quality traits have been planted in 17 countries on 6 continents and represent over 81 million ha (Manjunath, 2005). The impact magnitude of GM crops on the landscape has the potential to reduce biodiversity by increasing agricultural intensification, gene flow, and toxicity to nontarget organisms from herbicide-resistance, insect-resistant, and disease-

resistant crops. Currently GM crops coexist with organic production, and conventional agriculture (Altieri, 2005). Transgenic plants may generate unintended nontarget effects (Pilson and Prendeville, 2004). The escape of transgenes, conferring insect resistance, herbicide resistance genes, and stress-tolerance genes into wild populations via hybridization and introgression, may increase weeds populations by enhancing their fitness in the environment.

Five categories of risks related to the release of transgenic crop plants have been discussed (Hedge and Ellstrand, 2002; Altieri, 2005; Manjunath, 2005). The potential risks include: (1) Gene flow from transgenic crops to wild species and subsequent spread through horizontal transfer, seed or pollen dispersal. Horizontal transfer means the nonsexual transfer of transgenes from one organism to another. This type of transfer is more important for sunflower since sunflower is an open-pollinated crop and has many wild relatives. The gene flow may impact the farming practices in developed countries. (2) Impact of transgenic products on nontargets. Nontargets refer to the organisms that are present in cropping systems such as beneficial insects that are not the intended targets of engineered genes. The impacts include unintended detriment or benefit to the nontargets. (3) Direct risks from the transgenic crops. The transgenic product may have detrimental effects on human health or a transgenic plant may itself become an environmental problem if ecological performance is altered by the transgene. For example, Brazil nut albumin-transgenic soybean seeds have the potential to cause food allergies (Nordlee *et al.*, 1996). A transgenic food product containing antibiotic resistance markers may have risk by reducing the ability of antibiotic drugs to control pathogens causing human diseases. (4) Risks from the increased use of herbicide. This risk includes the exploitation of herbicide resistance traits that enable the use of herbicides on crops that were historically susceptible to a given herbicide. (5) Evolved resistance in the targeted pests. Resistance may occur in organisms targeted by the transgenes and is a potential environmental hazard that requires new control strategies or chemicals. Insect, pathogens, and weeds all have the ability to evolve new resistance. This is an important resistance management consideration.

It is important to keep the potential risks in mind when pursuing the transgenic approach for improving sunflower. However, not all of the risks apply to sunflower or to sunflower-specific transgenic traits. The risks depend on the transgene and the trait target. Clearly, there is much work ahead before the commercialization of a transgenic sunflower product is realized. However, given the enormous adoption and utilization of GM crops without any reported deleterious impacts to humans, it is clear that the benefit to humanity warrants further development in this exciting field.

3.3 New Technologies for Transgenic Breeding

3.3.1 Chloroplast transformation

Organelle inheritance is strictly maternal and genomes of organelles are often inherited uniparentally. Therefore, engineering chloroplast or mitochondrial genomes may provide a practical solution to the gene flow problem. This new transformation method is especially important for sunflower biotechnology. Although not yet reported in sunflower, stable transformation of chloroplasts in other higher plants has been reported (Svab *et al.*, 1990; Daniell *et al.*, 2004; Maliga, 2004). Rieseberg *et al.* (1991) and Rieseberg and Arias (1992) have studied the sunflower genetics of chloroplast genome, and Wills *et al.* (2005) describe chloroplast SSR polymorphisms in the family composite and the mode of organelle inheritance in sunflower. This research provides the best evidence to date that organelle gene containment may be a viable strategy in sunflower.

Gressel and Al-Ahmad (2003, 2004) described molecular solutions for increasing biosafety of transgenic plants. There are many ways to prevent transgene introgression from crops to other species, or to related weeds or wild species (containment strategies). These strategies are of particular importance for sunflowers. Once a transgene escapes, there is potential for it flowing into unintended species unless mitigated by some other containment strategy. To promote the development of transgenes in sunflower and

other crops, attention must be given to technology that can solve the gene flow problem.

3.3.2 Transformation efficiency and selection markers

One bottleneck of sunflower biotechnology is transformation efficiency. Optimization of the conditions for particle bombardment and identification of suitable genotypes and tissues for *Agrobacterium*-mediated transformation should improve overall transformation efficiency. Combinations of these methods may also enhance efficiency (Bidney and Scelonge, 1997; Pugliesi *et al.*, 2000).

For *Agrobacterium*-mediated transformation, systematic studies to identify the optimum tissue type, genotype, *Agrobacterium* strain, wounding method, medium, and binary vector are required for developing an ideal transformation method. Transgenic plants generated through *Agrobacterium*-mediated transformation may contain unwanted oncogene sequence from *Agrobacterium*, which may mediate gene transmission to other organisms that impact water, soil, and even humans. Therefore, the transformation method should include steps to completely eliminate unwanted sequence to prevent the unintended movement of transgenes to other organisms. *Agrobacterium* can be eliminated with antibiotics (Cubero and López, 2004). Extra DNA sequence from *Agrobacterium* may be delivered into transgenic tissues and the sequence can be detected and characterized via PCR assay (Cubero and López, 2004).

Antibiotic and herbicide resistance genes are often used as selectable markers for identifying transgenic plants. These genes have the potential to impact humans and other nontarget organisms or to impact the environment. Therefore, transgenic products should not contain such marker genes. Ebinuma *et al.* (2004) have developed a vector-based method to produce marker-free transgenic plants. The method utilizes the oncogenes of *Agrobacterium* and a site-specific recombination system to eliminate the marker genes. This system can also increase regeneration frequency. Positive selection, such as the OXO-transformation method (Lu *et al.*, 2000; Scelonge *et al.*, 2000), is another way to get marker-free transgenic plants.

3.3.3 Transgene expression

Stable expression of the desired transgene in transgenic plants is critical for success. In general, the promoter determines the pattern and level of the transgene expression. There are constitutive, tissue-specific, and inducible promoters available for developing transgenic sunflower. Limiting transgene expression to targeted tissues can reduce the potential negative impacts of the transgene on other traits. The site of transgene integration in the sunflower genome can also influence the pattern and level of expression. To mitigate these problems, a number of transgenic events are often generated with a given construct and only the event with the best performance is selected for product development. Multiple copies of the transgene can co-exist in a single transgenic event. In general, single copy events are preferentially selected for product development to prevent potential co-suppression of the transgene.

Most transgenic crops contain only one transgene that codes for pest resistance, herbicide tolerance, or other traits. In order to compound the benefits of multiple novel traits, more than one gene is sometimes used in the development of new transgenic products. This can be achieved through the construction of vectors with more than one beneficial transgene or can be achieved by stacking or pyramiding proven transgenes through conventional breeding. Transgene stacking is a useful technology for developing traits that are controlled by unrelated genes. For example, stacking a *Bt* gene and an herbicide resistance gene in corn can produce transgenic corn plants with both enhanced insect and herbicide resistance (Castle *et al.*, 2006). This technology might also be utilized to develop transgenic sunflower plants that produce high levels of latex in the leaves and stems for rubber manufacture and enhanced fatty acid profiles in the seeds for the manufacture of biofuel.

3.3.4 Gene shuffling technology

Gene shuffling is a process of producing a large array of many variants of DNA sequences from a gene or a gene family, and then reassembling the gene from random fragments by recombination (Stemmer, 1994; Castle *et al.*, 2004). The

recombinant genes can be screened in bacterial or other systems to identify the best version of the target gene. This technology has been successfully applied in various areas including herbicide resistance gene (Castle *et al.*, 2004). A weak glyphosate acetyltransferase (*GAT*) was improved 7000-fold through the shuffling technology and the improved *GAT* is being transformed into corn, soybean, and other crops for improved glyphosate herbicide resistance by Pioneer Hi-Bred International Inc., a DuPont company (Castle *et al.*, 2004; Siehl *et al.*, 2005). This optimized *GAT* gene can be transformed into sunflower for achieving a high level of glyphosate herbicide resistance. One of the challenges for oil composition modification in sunflower and other oilseeds is increasing the level of the new fatty acids. This shuffling technology can facilitate improving the activity of various desaturases for producing healthier oils or more useful industrial oils.

3.3.5 RNA interference technology

RNAi technology is a double-stranded RNA-induced and small RNA-mediated gene silencing (Cerutti, 2003), and the RNAi machinery is present in sunflower (Hewezi *et al.*, 2005). As indicated in the oil modification session, RNAi technology is very useful for modifying oil composition (Singh *et al.*, 2000; Bidney *et al.*, 2002). This technology also has great potential for engineering other traits in sunflower including resistance to disease, insect resistance, and herbicide. For example, expression of double-stranded RNA of a broomrape essential gene in sunflower may control the weed broomrape through uptake of specific dsRNA and subsequent silencing of the essential gene in broomrape through RNAi mechanisms.

3.3.6 Molecular marker-assisted selection

Conventional breeding has relied primarily on phenotypic selection of superior progenies from hybridization between two inbred lines. Although this breeding method has been very successful and has resulted in crops with improved yield and other agronomic traits, selection is often complicated

by environmental variance that creates obstacles to the evaluation of complex quantitative traits like yield and disease resistance. Sunflower breeding programs have been significantly enhanced through the use of molecular markers including RFLP, RAPD, SSR, and single nucleotide polymorphism (SNP). Some traits are controlled by single genes but many important agronomic and quality traits are controlled by multiple genes. Following the inheritance patterns of the QTL using molecular markers can assist selection for these loci in a breeding program. This process is called MAS for QTL and has the potential to both increase genetic gain in plants and enable breeders to identify genes contributing to traits like yield. The recent, rapid evolution of marker technology has fostered the identification and sequencing of valuable trait loci and the definition of heterotic groupings in crops where hybrid breeding is established. It has also enabled MAS techniques that permit breeders to identify desirable progeny earlier in the breeding process, and facilitates trait integration programs that permit the conversion of proven elite lines to isogenic sister lines with added traits of value (Tanksley *et al.*, 1998; Rommens and Kishore, 2000; Perez-Vich *et al.*, 2004a, b). MAS technology has been used in sunflower breeding for various disease resistance traits (Lawson *et al.*, 1998; Brahm *et al.*, 2000). With the development of an array of molecular markers and a dense genetic map of the sunflower genome, MAS for both single genes and QTLs is now possible (Babu *et al.*, 2004). MAS in combination with transgenic technology have the potential to greatly accelerate sunflower product development. Precise markers can be designed with transgene sequence that can facilitate the rapid introgression of transgenes into multiple genetic backgrounds. More importantly, MAS can greatly enhance transgene stacking for the development of sunflower products with multiple added-value traits.

3.4 Future Perspectives

1996 was a landmark year in the history of biotechnology. In that year, four transgenic crops with transgenic insect and herbicide resistance received regulatory approvals and were commercially planted in the United States. The transgenic

approval process in general required some 14 years of intensive research to demonstrate that a novel transgenic product is both beneficial to farmers and safe for humans, animals, and the environment (Manjunath, 2005). The crops included corn hybrids that expressed a *Bt*-protein for protection against European corn borer (*Ostrinia nubilalis*); potatoes expressing *Bt*-proteins to protect against the Colorado potato beetle (*Leptinotarsa decemlineata*); cotton expressing *Bt*-proteins to protect against a host of pests including tobacco budworm (*Heliothis virescens*), bollworm (*Helicoverpa zea*), and pink bollworm (*Pectinophora gossypiella*); and soybean with transgenic resistance to the broad spectrum herbicide glyphosate (Manjunath, 2005).

During the last 10 years additional crops with improved transgenic insect and/or herbicide resistance and other traits have been developed and commercialized in the United States and other countries. In addition, corn and soybean varieties with multiple transgenic trait stacks have also been commercialized. The area planted to transgenic crops is steadily increasing and more and more countries are issuing approvals that will permit even greater adoption of the technology in the future (James, 2004; Manjunath, 2005; Castle *et al.*, 2006). The planted area of transgenic crops increased from 1.7 million ha in 1996 to 81 million ha in 2004 and the number of countries growing transgenic crops increased from 6 in 1996 to more than 17 in 2004 (James, 2004). The crop that leads in overall cultivated area is soybean with transgenic herbicide resistance. Benefits from these transgenic crops include improved weed and pest management, higher yields, and greater profits to the growers. These benefits and the amelioration of some negative environmental impacts from agriculture, such as soil erosion and wide spectrum pesticides, have significantly promoted the adoption of transgenic crops globally. In 2004, Ford Runge and Barry Ryan summarized the global transgenic research and status: at least 63 countries have initiated transgenic approvals for commercialization of some 57 different crop plants. More and more people are realizing the benefits of transgenic crops. The world population will likely reach 9.3 billion by the year 2050 and food demand will double from its current level as the population grows. Transgenic crops have the potential to help

meet this increased food demand and prevent the risk of an unstable future. The amount of arable land available for agriculture is steadily decreasing each year as industrial, residential, recreational, and other needs lead to conversion of farmland into parking lots, strip malls, and housing complexes. Currently about 852 million people in developing countries suffer from malnutrition. About 1.4 million women (about 22% of world population) suffer from anemia caused by iron deficiency. About 140 million children suffer from vitamin A deficiency. More than 30% of crop losses in agriculture are attributable to biotic stresses such as disease, insects, and weeds and abiotic stresses such as drought, cold, heat, salinity that might be overcome through transgenic research (Manjunath, 2005). There is an increasing need to produce more food that is more highly nutritious from a shrinking arable land base.

A transgene can come from any organism and biotechnology eliminates the reproductive and phylogenetic barriers that have limited success through traditional breeding. The first generations of transgenic crops with enhanced insect or herbicide resistance have already provided beneficial traits to farmers and end users. In the future, transgenic crops with enhanced tolerance to environmental stresses such as drought, and/or with enhanced nutritional value, and/or with improved properties for industrial uses such as biodiesel may be achieved. Hedge and Ellstrand (2002) discussed potential benefits of transgenic crops by comparing them to their conventionally derived counterparts. They listed four primary benefit categories:

1. Benefits from increased yields. Meeting the demand for increased food supplies by a growing human population is considered as one of the major environmental threats of the future (Clout, 1999). Transgenic traits have provided an efficient method for increasing crop yield. *Bt*-corn and *Bt*-cotton are good examples where yield losses from predatory insects have been reduced using transgenic technology. Yield gains from the use of insect-resistant transgenic plants provide indirect benefits to the environment by reducing the need for further exploitation of land that is not currently under cultivation. This is most important in developing countries

(Alexandratos, 1999). Yield enhancement can postpone the conversion of wild lands to agricultural production and maintain balanced ecological environments.

2. Environment protection from agricultural chemicals. One of the major concerns for conventional agriculture is the heavy use of insecticides, fungicides, and nematicides that can pollute water, air, and soil environments. *Bt*-technology can enhance the ability of crops to withstand pests, thereby benefitting the environment by reducing insecticide use. The commercialization and widespread use of *Bt*-corn and *Bt*-cotton has significantly reduced the amount of insecticides used on these crops in the United States and other countries.
3. More efficient use of renewable resources such as land, water, and soil nutrients. Soil erosion in conventional industrial agriculture can occur 100 times faster than the rate of soil formation (NRC, 1989). The rapid rate of soil erosion has enormous potential to reduce the productivity of soils and contributes to the sedimentation in streams and pollution through run off that negatively impacts aquatic ecosystems. The advent of no-till agriculture in the United States has resulted in a number of economic and environmental benefits. The cultivation of transgenic herbicide-resistant corn and soybean has greatly contributed to the increase of no-till agricultural systems that help reduce or eliminate soil erosion. Transgenic plants that have enhanced resistance to root diseases could further increase the prevalence of no-till agricultural systems.
4. Monitoring of environmental pollution using pollution-sensitive transgenic plants. Transgenic plants have the potential to be used for detecting and even remediating environmental pollution. Transgenic tobacco plants can serve as monitors of heavy metal concentrations in soils and may serve as visible indicators of temperature or moisture levels in the environment.

In addition to the benefits described above, transgenic crops can significantly benefit human life by providing more nutritious and healthy foods, desirable fruits, and valuable industrial products. High oleic soybean (Cahoon, 2003; Kinney, 2003) and transgenic tomato (<http://>

www.ars.usda.gov/is/AR/archive/sep00/tomato0900.htm) with long shelf life are good examples that illustrate the benefits of transgenic crops to human life. Sunflower is one of the world's four most important oilseed crops, with an estimated value of \$40 billion per year and provides a source of premium vegetable oil, confectionery food and ingredients for various industrial products. Biotechnology has the potential to help evoke the full potential of this valuable crop. With the increases in demand for petroleum that are expected in the future, it is likely that government and industry will continue to support biofuel development including biodiesel made from sunflower. Latex from sunflower has the potential to be improved and exploited for domestic rubber manufacture and the promise of specialty oils with a myriad of industrial applications will further drive the development of new sunflower products. As new products are developed, transgenic approaches have the opportunity to play a pivotal role in their development.

Public acceptance of genetically modified crops varies and some people are opposed to the use of biotechnology for crop improvement. The reluctance to accept biotechnology in agriculture is often attributed to a lack of sufficient and accurate information in the public sector (Bruening, 2000; Hino, 2002). For example, Hollywood films depict GMOs as terrifying scientific accidents in movies like "Spider Man" and "Corn". These films are not based on science and can mislead the public into believing that any manipulation of DNA is extremely risky and may lead to disaster (Byrne, 2006). The good news is that universities and biotechnology companies have initiated efforts to educate the public with a series of lectures on biotechnology. Like other technologies, it will take time for biotechnology to be dominantly accepted by the public.

Intellectual property protection is another hotly debated topic related to biotechnology. A training handbook is available (<http://www.dfat.gov.au/publications/biotech/index.html>) and a recent review has summarized and discussed intellectual property issues (<http://www.dfat.gov.au/publications/biotech/index.html>) in the regulation of genetically engineered plants and animals. Intellectual property takes important roles in economic growth and advancement in the biotechnology sector. Patents protect researchers'

new ideas and products and provide incentives for private sector investment into biotechnological research and product development.

New technological developments should accelerate the discovery of new trait genes, expression tools, efficacious transformation methods, and methods for breeding transgenes into elite lines. Advancements in sunflower structural and functional genomics have lagged behind advancements in crops such as maize, rice, and soybean, in part due to a lack of financial support for investments in the crop and its relatively large genome size. Fortunately, the technologies and tools that have already been developed in other crops can be easily adapted to sunflower research. Gene flow is a particular issue for sunflower biotechnology. Therefore, efforts should be directed toward developing methods for preventing transgene introgression from sunflower to related weeds or wild species. Chloroplast transformation is one of the relevant techniques that may facilitate this end. Many trait genes from sunflower and other crops are available for improving productivity and quality in the crop. In the sunflower industry, transgenic initiatives like the ones listed in Table 4 have already begun and sunflower biotechnologists have gained considerable knowledge, methodologies, and tools for developing novel transgenic products. Molecular breeding and transgenic approaches can be synergistic in product development. In the near future, sunflower biologists will be able to generate transgenic sunflower varieties that have increased grain yield through enhanced resistance to abiotic and biotic stresses and produce high quality seeds with more useful fatty acid profiles. The great potential of rubber and biodiesel from sunflower will likely advance sunflower biotechnology to a bright new era and foster the development of "industrial sunflower" with enhanced oils for biofuel in the seeds and enhanced latex content in leaves and stems for rubber manufacture; all the while inspiring the imagination of artists with its beautiful floral magnificence.

ACKNOWLEDGEMENTS

We thank Dennis Bidney, Xu Hu, Glenn Cole, Mark Mancl, Nasser Yalpani, Jon Duvick, Oswald

Crasta, Otto Folkerts, Chris Scelonge, Zhongmeng Bao, Dan Altier, Lijuan Wang, and Guru Rao for their contributions to the research with *Sclerotinia* and insect resistance traits in transgenic sunflowers. Thanks to Xu Hu and Dennis Bidney for sharing unpublished information, and Beth Allen and Ken Braun for literature search. Thanks to Gusui Wu, Dave Charne, Linda castle, and Natalie Derry for their critical review of the manuscript.

1. INTRODUCTION

Peanut, or groundnut, is a New World legume that is believed to be native to South America. Discovered in the 1500s by early Spanish and Portuguese explorers as an extensively cultivated crop of the Indians in the West Indian Islands, Mesoamerica, and South America, peanut was disseminated throughout Europe and eventually traveled to the seaboard of the southeastern United States. Cultivated peanut, *Arachis hypogaea* L., has since become the third most important oilseed grown in the world, serving as an important food source for millions of people living in semiarid and tropical regions. As a significant source of proteins, vitamins, and minerals, peanut is used for human and animal consumption as well as in soaps, detergents, and cosmetics. This chapter discusses the origin and history of the peanut, progress toward improving the crop through traditional breeding, and the role of transgenic breeding in future peanut germplasm improvement.

1.1 History, Origin, and Distribution

There is little doubt that the peanut, *A. hypogaea* L., is of South American origin. Although the crop was referred to by various names, evidence to

support its presence in South American countries is abundant in the 16th and 17th century literature. The first recorded report of the peanut appears to be one written by Captain Gonzalo Fernandez de Oviedo y Valdes, a historiographer of the Indies. In 1535, he wrote of a fruit named “mani”, which was sown, grown underground, and upon harvesting, yielded fruit about the size of pine nuts, but in shells (de Oviedo y Valdes, 1535/1547). The Amerindian name “mani” for peanut is still used in Cuba and Spanish South America today. An extensive review of early post-Columbian records reveals many references to peanut and its cultivation (Hammons, 1973, 1982) indicating the crop’s widespread geographical distribution before the discovery of America. Peanut cultivation was reported in Peru, Hispaniola, Rio de Janeiro, Mexico, Brazil, Spain, the West Indies, and the La Plata basin in the 1500s. By the 17th century, production of peanuts had spread to Jamaica, Barbados, Guadeloupe, the French Antilles, and Pernambuco, with the first published report of cultivation in the Americas occurring around 1640.

Archeological evidence of peanut cultivation also points to a South American origin. The earliest history of the crop is revealed in art and artifacts of the early Peruvian civilization along the eastern slopes of the Andes, dating back to approximately 3900–3750 years before the present

(Hammons, 1994). Well-preserved groundnuts in terracotta jars and funerary vases decorated with well-sculptured groundnut pods reveal the esteem to which the crop was held by those cultures. Bird (1948, 1949) discovered evidence placing the appearance of peanuts in Peru prior to maize and warty squash, somewhere around 1200–1500 BC. The discovery of ethnobotanical remains established the presence of peanuts as a cultigen in the Tihuacan valley of Mexico at approximately 100 AD, although the evidence suggests that it was introduced as a minor crop there. As of yet, phytomorphic representations and ethnobotanical remains of peanuts in Brazil and Bolivia have not been discovered, but the climate in those countries is less favorable for the preservation of plant remains. For the most part, archaeological evidence concerning peanuts is supported by natural historians and other disciplines.

Although the exact geographical origin of peanut is not known, we know that the crop has been under cultivation for more than 3500 years and has been widely dispersed through human migration and crop exchanges. All wild species of the genus *Arachis* are found in South America and are distributed from northeastern Brazil to northwestern Argentina and from the south coast of Uruguay to the northwestern Mato Grosso (Gregory and Gregory, 1979; Gregory *et al.*, 1980). The cultivated peanut, *A. hypogaea*, was first described by Linnaeus (1753) and is believed to have originated in southern Bolivia (Krapovickas, 1968; Cardenas, 1969).

Dissemination of the cultivated peanut from South America began with Europe and spread to both coasts of Africa, Asia, the Pacific Islands, and eventually to the southeastern United States. At least two distinct forms, a 2-seeded Brazilian and a 3-seeded Peruvian type, were distributed (Dubard, 1906). The first introduction of the groundnut into Europe was reported by Nicolas Monardes in 1574 (Hammons, 1994). Early European peanut cultivation was further documented by Krapovickas (1968) based on reports that a Spanish type of seed came from Brazil to Portugal and then to Rome. The Portuguese have been credited with enriching African agriculture by introducing peanut there from Brazil and possibly to other lands as well. Most believe the first introduction of peanuts into the United States occurred when slave ships from

Africa arrived in the 1700s. The earliest full-season peanut reported in the United States was a small-podded runner type (var. *hypogaea*), which was cultivated in the southeast and probably came from Africa, but has characteristics similar to those described for peanuts found in the West Indies (Hammons, 1994). Large-seeded Virginia-type (var. *hypogaea*) peanuts are thought to have originated in Bolivia and were cultivated in the United States as early as 1844. Spanish peanuts (var. *vulgaris*), which were first cultivated in Europe by Spaniards and thus termed “Spanish”, require a shorter growing season and were introduced to the United States from Malaga, Spain, in 1871. Valencia (var. *fastigiata*) peanuts were coined so by Beattie (1911) due to their introduction into the United States in the 1900s from Valencia, Spain. Introduction of the peanut into India, credited to the Spaniards, is believed to have occurred in the middle 1800s, with the first large scale production (4000 acres) being reported in India in 1850–1851.

1.2 Botanical Description

The genus *Arachis* L. belongs to the family Leguminosae and comprises a large and diverse group of diploid and tetraploid taxa in excess of 50 species, which are naturally dispersed in Argentina, Bolivia, Brazil, Paraguay, and Uruguay. The diversity of this genus is evident by the numbers of annuals and perennials it comprises and their varied forms of reproduction. Most *Arachis* species reproduce by seeds, but some are rhizomatous and reproduce largely through vegetative means. Members of the genus are identified and characterized by their alternately attached basal and dorsal anthers, flowers in terminal or axillary spikes, and pinnate stipulate leaves and leaflets. The “peg”, which results from the expansion of the intercalary meristem at the base of the ovule, is unique to the genus and results in a lomentiform carpel (pod), which contains one to five seeds, each comprises two large cotyledons and a straight embryo. The generic description of *Arachis* given by Bentham and Hooker (1867) is as follows:

Cotyledons thick, fleshy; radical very short; low suberect herbs, often prostrate; leaves abruptly bipinnate, leaflets in 2 pairs or rarely trifoliate, estipulate, stipules adnate to the petiole at the base. Flowers crowded into a dense axillary spike,

sessile at the leaf axile or the biauriculate bract or very shortly pedicellate. Bracteoles below the calyx linear. Calyx tube filiform, lobes membranaceous, the 4 upper ones connate, the lower one slender, separate. Petals and stamens inserted at the apex of the tube, standard suborbicular, wings oblong, free, keel incurved, prostrate. All stamens connate into a close tube, occasionally one absent; anthers alternate, elongate, subbasifixed, the alternate ones versatile. Ovary subsessile toward the base of the calyx tube, two to three-ovuled. After the fall of the flower ovary shows toward a stalk, the torus, which elongates and becomes reflexed and rigid and the ovary is continuous with the same, acute at the apex, and after the fall of the style ends in a stigmalike callus; the style is long, filiform with a minute terminal stigma; the pod ripens inside the soil and is oblong, thick, indehiscent, subtorulose but not articulate, and continuous inside. Seeds 1-3, irregularly ovoid.

Cultivated peanut, *A. hypogaea* L., is not known to occur in the wild state but is presently cultivated in over 80 countries in tropical and warm temperate regions of the world. *A. hypogaea* L. was the first *Arachis* species to be described by Linnaeus and is one of four tetraploid ($2n = 4x = 40$) *Arachis* species, the other three being *A. monticola*, *A. glabrata*, and *A. hagenbeckii* (Smartt and Stalker, 1982). Most other *Arachis* species are diploid, having a $2n = 2x = 20$ complement of chromosomes. Cytological characterization of *A. hypogaea* L. reveals two distinct pairs of chromosomes, one termed the A genome, is smaller than any other pair, and the other termed the B genome, has a secondary constriction and is satellited (Husted, 1933, 1936). Thus, the cultivated peanut is an allotetraploid, which combines the A and B genomes. The presence of an A genome in all examined *Arachis* material except *A. batizocoi* was later confirmed (Smartt *et al.*, 1978a, b). The exact origin of the A and B genomes remains unclear. However, four A genome species, *A. cardenasii*, *A. chacoense*, *A. correntina*, and *A. duranensis*, and two B genome species, *A. batizocoi* and *A. impaensis*, have been identified as possible progenitors of *A. hypogaea* L.

A. hypogaea L. is divided into two subspecies, *hypogaea*, which is further divided into four botanical varieties, and *fastigiata*, which is made up of two varieties. The subspecies *hypogaea* has alternate branching, an absence of flowering along the main stem, and either a spreading (prostrate)

or bunching growth habit. One botanical variety within this subspecies, *hypogaea* var. *hypogaea*, encompasses the Virginia and runner peanut market types. Another botanical variety, *hypogaea* var. *hirsuta*, comprises the Peruvian humpback or Chinese dragon types. Two other botanical varieties exist under the subspecies *hypogaea*: var. *aequatoriana* and var. *peruviana*. Seed from the *hypogaea* subspecies requires a dormancy period after maturity before germination. The *fastigiata* subspecies is characterized by sequential branching, flowers on the main stem, little or no seed dormancy, and an erect growth habit. The two botanical varieties within the *fastigiata* subspecies are *fastigiata* (Valencia market type) and *vulgaris* (Spanish market type) (Krapovickas and Gregory, 1994).

Cultivated peanuts are either erect or prostrate and usually 6–24 in. (15–60 cm) in height (Figure 1). Peanut plants produce one well-developed tap root system with many lateral roots that are generally sparsely hairy. Nodules

Figure 1 Graphic illustration of a peanut plant [Reproduced from http://www.enchantedlearning.com/.../Peanutplant_bw.GIF. © EnchantedLearning.com]

where nitrogen fixation takes place are formed by the symbiotic bacteria belonging to the genus *Rhizobium* and are normally found on the roots. Arranged alternately on the stems, peanut leaves have four leaflets arranged in opposing pairs. Leaves are normally borne on slender, grooved and jointed rachis, subsessile, elliptic, and stipulate (Ramanatha and Murty, 1994). Flowers occur on inflorescences located in the axils of the leaves and are never born at the same node as vegetative branches. Each flower has five petals at the top of the calyx tube, ten stamens, and a pistil composed of an ovary, a style, and a stigma. The first flowers appear 4–6 weeks after planting. Anthesis and self-pollination usually occur at sunrise with pollination taking place within the closed keel of the flower. After fertilization, a pointed gynophore, commonly known as the “peg”, develops, elongates, and enters the soil where pod growth begins. Spanish and Virginia market types require less time to produce mature seed (90–120 days) compared to runner market types, which generally require 130–150 days after planting (DAP). Boote described the growth stages of peanut in 1982 (Boote, 1982), dividing them into two categories: vegetative and reproductive (Table 1).

1.3 Economic Importance

Peanut is grown on approximately 37 million acres worldwide and is the third major oilseed crop, surpassed only by soybean and cotton. China leads the world in peanut production and exports, producing over 13 million metric tons in 2004 (Table 2). Peanut acreage in China accounts for 25% of that for all oil seed crops. Production there has increased greatly since 1961, when production was reported to be just over 1 million metric tons. Peanuts can be grown in most provinces of China, but most production occurs in the summer and in one of two geographic regions separated by the Yangtze river. At least half of the peanuts grown in China are used for oil where the majority of peanuts grown are of the intermediate runner and Spanish types. Second only to China, India is now the second largest peanut producing nation in the world, harvesting almost 7 million metric tons in 2004. Peanut accounts for approximately 50% of oilseed production in India, and like China, half of the peanuts produced are used for oil production. Five states, namely, Gujarat, Andhra Pradesh, Tamil Nadu, Karnataka, and Maharashtra, account for almost 90% of India's production, where peanuts are grown during the

Table 1 Growth stages of peanut^(a)

	Abbreviated title of stage	Description
Vegetative stages		
VE	Emergence	Cotyledons near soil surface with seedling showing; some part of plant visible
VO		Cotyledons flat and open at or below soil surface
V-1 to V-(N)	First tetrafoliate to Nth tetrafoliate	One to N developed nodes on the main axis (node is counted when its tetrafoliate is unfolded and leaflets are flat)
Reproductive stages		
R1	Beginning bloom	One open flower at any node on the plant
R2	Beginning peg	One elongated peg (gynophore)
R3	Beginning pod	One peg is the soil with turned, swollen ovary at least twice the width of the peg
R4	Full pod	One fully expanded pod, to dimensions of cultivar
R5	Beginning seed	One fully expanded pod in which seed cotyledon growth is visible when the fruit is cut in cross section (past the liquid endosperm stage)
R6	Full seed	One pod with cavity filled by the seeds when fresh
R7	Beginning maturity	One pod showing visible natural coloration or blotching of the inner pericarp or testa
R8	Harvest maturity	Two-thirds to three-fourths of all developed pods showing coloring of pericarp or testa
R9	Over-mature pod	One undamaged pod showing orange-tan coloration of testa or natural peg deterioration

^(a)Reproduced from Boote (1982)

Table 2 Peanut production, 2004^(a)

Countries	Production (t)	Harvest (ha)	Yield (kg ha ⁻¹)
China	13 420 000	5 057 000	2650

kharif (rainy) season (<http://www.lanra.uga.edu/peanut/knowledgebase>). Although India is the second largest peanut producer in the world, the inability to rid its crop of aflatoxin accumulation limits the amount of product exported.

The United States ranks third among peanut producing countries, with the majority of its peanut acreage distributed across the southeastern region of the nation. Although the United States does not lead the world in peanut production, it has ranked first in yield per land unit for over 15 years. Peanut is ninth among major row crops being grown in the United States and was second in dollar value per acre prior to the passing of the Farm Security and Investment Act of 2002, but has dropped in the rankings since then due to the elimination of the price support system. Historically, the bulk of peanut production in the United States is concentrated geographically in specific counties of seven states: Alabama, Florida, Georgia, New Mexico, North Carolina, Oklahoma, and Texas. Georgia leads the United States in peanut production acreage cultivating approximately 755 000 acres in 2005 (http://www.nass.usda.gov/Statistics_by_State/Georgia/index.asp). All four market types of

peanut are grown in the United States with the southeast producing mainly runner types, the Virginia–Carolina region producing Virginia and runner types, and the southwest producing Spanish, runner, and Valencia types.

Production of peanuts is generally conducted in the warm temperate regions of the world. In fact, temperature is the major limiting factor for peanut yield since a minimum of 3000 growing degree days (with a base of 50 °F) are required for peanut growth and development (Ketring and Reid, 1995). The seasonal amount of water needed for peanut production is 16–30 in., with the limits depending upon environmental conditions such as air and soil temperature, wind, and radiation. Many peanut production areas receive the required amount of natural rainfall needed for crop production (dry land production) and others must be irrigated.

To begin a growing season with a healthy crop, high-quality seeds with at least 80% germination rate are needed. In the United States, optimal conditions for planting generally occur in early to late spring (Shokes and Melouk, 1995). Adequate soil moisture and a minimum soil temperature of 60 °F are necessary for germination but emergence rapidly increases if soil temperatures are above 70 °F. Growth rates vary with market type but in general, Spanish and Virginia market types require less time to produce mature seed (90–120 days) compared to runner market types, which generally require 130–150 DAP. As the growing season ends, the maturity of peanuts within the pods can be predicted using a hull-blast method developed at the University of Georgia (Williams and Drexler, 1981). When ready to harvest, peanut plants are generally dug, inverted, and left to dry or “cure” in “wind rows” in the field until acceptable moisture content is met. For maximum yield and quality, peanuts should be dug prior to a hard freeze. Freezing temperatures reduce peanut germination, seedling vigor, and metabolic processes as well as reduce the strength of the shoot–root juncture, resulting in yield loss when that connection is severed during digging.

All aspects of peanut production are subject to different types of biotic or abiotic stresses and/or constraints. Biotic stresses vary depending upon the part of the plant affected and the growing region. Biotic agents that affect peanut production include insects, fungi, bacteria, virus, nematodes,

and weeds. A complete list of pathogens affecting peanut as well as the part of the plant and the most common growing region affected has been compiled (Kokalis-Burelle *et al.*, 1997) as well as suggestions on disease management (Melouk and Shokes, 1995). As with most crops, weed control is important during peanut cultivation (Buchanan *et al.*, 1982; Brecke, 1995). Weeds cause yield loss and difficulties during harvest. Most programs for weed control involve a combination of crop rotation and herbicide treatment. Herbicide rotation is also important to prevent the development of resistant weed species, a situation that is becoming increasingly problematic with *Amaranthus* spp. (common name Pigweed) in the United States.

All parts of the peanut plant can easily be utilized. The intact vines of the wild *Arachis* species can serve as excellent forage for horses and ruminant livestock. In fact, in some areas of the United States, peanut is becoming more popular as a forage crop. Florigraze is a perennial peanut cultivar (*Arachis glabrata* Benth.), which is primitive when compared to the common cultivated peanut and produces very few seed in comparison. Released by the University of Florida, Florigraze (Prine *et al.*, 1986) was grown on over 26 000 acres in Florida in 2005. Acreage planted in Florigraze is also on the rise in the coastal plains region of Georgia and across the US gulf coast as far west as Texas. The hay of Florigraze and Arbrook (a more recent University of Florida release; Prine *et al.*, 1990) contains 13–20% crude protein and has amino acid and mineral composition similar to that of alfalfa. The shells or pods of the peanut can also be used as livestock feed, burned as fuel, or made into particle board. Other nonfood products that can be made from peanuts include soaps, medicines, cosmetics, and lubricants.

Most of the peanuts grown in the United States are used for human consumption of the seed. The seed contains 25–32% protein and 42–52% oil and is a reasonably good source of dietary minerals. Peanuts have also been shown to be a good source of resveratrol, an antioxidant that has been linked to reducing heart disease and cancer (<http://www.peanut-institute.org/Plant.Compound.PR.html>). If cleared of aflatoxin contamination, raw peanuts have few antinutritional qualities, most of which

are associated with the testa or “skin” which is commonly removed during peanut processing. Peanut seeds can be used directly for food or can be crushed into oil and high-protein meal. Approximately two-thirds of the world’s peanut crop is crushed for oil (<http://www.lanra.uga.edu/peanut/knowledgebase>), which can be used for cooking, lighting, fuel, and as a food constituent. Recently, there has been a surge in interest in developing peanuts for the production of biofuel or biodiesel (<http://southwestfarmpress.com/news/110106-peanut-biodiesel>). Toward that end, research is underway to develop peanut cultivars that are higher in oil content than those currently available. In the United States, whole peanut seeds are chiefly roasted as shelled or in-shell seeds, used in candy, or made into peanut butter. The large nuts of the Virginia market type are generally sold roasted in the shell, where as the runner and Spanish market-type peanuts are used for candies, salted cocktail nuts, and peanut butter. Valencia peanuts are usually marketed as medium-sized in-shell nuts.

1.4 Traditional Breeding

Regardless of the crop, the goal of any plant-breeding program is to direct heredity in ways that improve the overall performance of the plant. In the past, this goal has proven difficult for peanut breeders due to the lack of genetic diversity among cultivated peanut lines. Simpson *et al.* (1975) listed the major obstacles to rapid progress in peanut breeding as being (1) lack of genetic and cytological information, (2) the complex nature of the species, (3) limited genetic variability, and (4) specific standards for commercial acceptance. Progress has been made since that time to lessen the burden of many of those obstacles, in part due to the increasing utility of molecular techniques with regard to peanut.

1.4.1 Breeding objectives

Objectives of peanut breeding programs have not changed drastically since they were outlined by Branch (1979) but have been re-examined by others (Knauff and Wynne, 1995). The goals of peanut breeders can be placed into

categories based on the intended beneficiary who may be a grower, a processor, or a consumer. Growers desire peanut cultivars with traits such as high yield, pest resistance, early maturity, and environmental stress tolerance. Processors want peanut cultivars with traits that streamline their practices. Such characteristics include uniform maturity, shelling, and blanching properties. Consumers and peanut product manufacturers prefer seed with improved nutritional qualities along with a pleasing color, shape, texture, and aroma. Recently, manufacturers have begun to demand that seed also have an oleic acid content of at least 70% (of the total oil), a quality that extends the shelf life of their products.

1.4.2 Yield, quality, and uniformity

Growers have historically yearned for peanut varieties with a high yield per land unit, but this need is becoming increasingly more urgent due to the rise in production costs (especially fuel) and the elimination of the price support system in the United States. Yields per acre in the United States have increased by 33% since 1995 (<http://www.usda.gov/nass>) but have remained steady worldwide in the last 3 years. Increasing yield in a peanut variety encompasses many different facets including developing disease resistance, shortening the required growing period, and increasing tolerance to environmental stresses such as drought. Three physiological processes have been identified as crucial to peanut yield (Duncan *et al.*, 1978): (1) partitioning of nutrients between vegetative and reproductive parts, (2) rate of fruit establishment, and (3) length of filling period. Much progress has been made toward increasing the percentage of assimilate directed toward reproductive plant parts. Percentage of fruit assimilate, which were at 41% for the first peanut cultivar, are now estimated at 98% for more recent releases (Norden *et al.*, 1982). In countries such as the United States, producers willingly participate in a “check-off” system where they place a percentage of their annual profits into programs coordinated by organizations such as the National Peanut Board (http://www.nationalpeanutboard.org/document_206.asp) to support further research on cultivar development and production improvement. Research aimed

toward the development of high-yielding cultivars is crucial to profitable peanut production as evidenced by the fact that peanut production in 2004 for the United States averaged 3540 kg ha⁻¹ compared to China's 2650 kg ha⁻¹ and India's 960 kg ha⁻¹ (Table 2).

1.4.3 Disease resistance

An important component of strengthening the production of any crop is the development of cultivars with disease resistance. Without the yield loss or input expenses due to disease and disease management, peanut production would be extremely profitable without a price support system in place. Peanut production can be inhibited by many pathogens such as fungi, virus, insects, bacteria, mycoplasma, and nematodes (Kokalis-Burelle *et al.*, 1997). The type of disease threat varies greatly upon the geographic location of the growing region. Still, only a few of the diseases caused by these pathogens are of worldwide importance and are the focus of peanut breeding programs.

Important fungal diseases infecting plant foliage include early leaf spot caused by *Cercospora arachidicola*, late leaf spot caused by *Cercosporidium personatum*, and rust caused by *Puccinia arachidis*. Soil-borne fungi of economic importance affecting peanut include *Sclerotinia minor* Jagger, which causes *Sclerotinia* blight, *Sclerotium rolfsii*, which causes southern stem rot, *Pythium myriotylum*, which causes *Pythium* pod rot, and *Cylindrocladium crotalariae*, which causes *Cylindrocladium* black rot (CBR). Greenhouse and laboratory tests for resistance to these fungal diseases have been developed and used to screen peanut germplasm prior to field testing and/or use in breeding programs (Melouk *et al.*, 1992; Shokes *et al.*, 1996; Chenault *et al.*, 2003). Through these research efforts, peanut varieties have been developed that demonstrate levels of resistance to fungal infection (Goldman *et al.*, 1995; Shew *et al.*, 1995). A molecular marker for *S. minor* resistance in runner, Spanish, and Valencia peanut market types has been developed which may be used for marker-assisted selection (MAS) to increase the efficiency of resistance breeding (Chenault and Maas, 2005). No cultivar has been developed with complete resistance and efforts continue toward

that end. Current management strategies for soil-borne and foliar fungal diseases include both cultivar selection and fungicide application.

Aflatoxin contamination of peanut caused by *Aspergillus flavus* infestation is a widespread serious problem in most producing countries where the crop is grown under rain-fed conditions. Aflatoxin contamination does not affect crop productivity but it makes the end product unfit for consumption as toxins are injurious to health. Aflatoxin contamination continues to be a severe pre and postharvest problem in the southeastern United States and in India, where it limits product export (<http://www.lanra.uga.edu/peanut/knowledgebase>). Screening for *A. flavus*-resistant germplasm has identified several sources of resistance (Mixon *et al.*, 1973; Mixon, 1979) among germplasm accessions. Efforts continue to mine the US national peanut germplasm collection (over 9000 accessions) for resistance to *A. flavus* (Holbrook *et al.*, 1997, 2000a, c; Xue *et al.*, 2004). Identification of *A. flavus*-resistant germplasm will always be a high priority of the peanut industry due to the fact that countries importing peanuts restrict the permissible limits of aflatoxin contamination of products.

Peanut is susceptible to a number of viruses, but tomato spotted wilt virus (TSWV) is the one with the largest economic impact. Prevalent on peanut in the southeastern United States, India, and other countries across the world, TSWV has a host range of over 400 plant species and is vectored by small insects called thrips (thysanoptera: thripidae). Losses incurred due to TSWV on peanut reached over \$40 million in Georgia alone in the late 1990s (<http://www.tomatospottedwiltinfo.org/peanut/management.htm>). Control of TSWV spread through insecticide application is not feasible and thus host plant resistance is the only viable disease management tool. Much success has been achieved in breeding peanut for TSWV resistance. The University of Georgia has developed a TSWV risk index to aid producers in that area in identifying and avoiding high-risk situations (Brown *et al.*, 2001). Although no available cultivar demonstrates complete resistance, moderate to high levels of field resistance to TSWV has now been incorporated in several peanut cultivars of different market types (Yancy, 2002). Several species of the root-knot nematode, *Meloidogyne*, inhibit peanut production in the United States and worldwide. The predominant

species affecting peanut is *Meloidogyne Arenaria*, which can cause yield losses exceeding 30% (Rodriguez-Kabana and King, 1985). Nematode attack damages the plant root system, which results in an overall decline of plant vigor and fruit production. Additionally, in this weakened state, the plant becomes more susceptible to other diseases such as soil-borne fungi. Host resistance to nematode infection was documented in wild *Arachis* species in the 1980s (Baltensperger *et al.*, 1986; Stalker and Moss, 1987; Nelson *et al.*, 1989) but was not documented in cultivated peanut until later (Holbrook and Noe, 1992; Holbrook *et al.*, 2000b). Since that time much progress has been made in breeding for resistance to *M. arenaria* including the development of molecular markers to identify resistant peanut germplasm (Burow *et al.*, 1996; Chu *et al.*, 2006) for use in breeding programs. This type of MAS has greatly enhanced the efficiency of breeding for nematode resistance. Peanut germplasm (Stalker *et al.*, 2002; Anderson *et al.*, 2006) and cultivars COAN and NemaTAM with nematode resistance (Simpson and Starr, 2001; Simpson *et al.*, 2003) have been recently developed.

1.4.4 Drought tolerance

In areas where natural rainfall does not meet the required amount needed for successful peanut production, fields must be irrigated to ensure crop survival. Energy costs for irrigation are a significant cost in peanut production, and availability of underground water is sometimes limited where peanut is cultivated. Thus, breeding for drought tolerance in peanut is a priority in regions where peanuts are not irrigated. Holbrook and Stalker have recently identified key areas of research regarding drought tolerance (Holbrook and Stalker, 2003). Germplasm with increased drought tolerance has been identified for use in breeding programs (Reddy *et al.*, 2001), and the expression of peanut genes in response to drought stress has been reported (Jain *et al.*, 2001).

1.4.5 Early maturity

In regions where growing seasons are shortened by environmental conditions such as freezing temperatures, and limited rainfall, peanut cultivars that mature early are a necessity. In general, most

Spanish cultivars mature at about 120–130 DAP, but few varieties of the other peanut market types mature before 140–150 DAP. The components of early maturity and their inheritance in cultivated peanut have been documented (Bailey and Bear, 1973; Upadhyaya and Nigam, 1994). Early maturing germplasm (Upadhyaya *et al.*, 2002a, b) and runner-type cultivars maturing at 125–130 DAP have been developed (Gorbet, 2003). A recent cultivar release “Wilson” by Mozingo *et al.* (2004), is described as a large-seeded Virginia-type peanut that matures at 135 DAP.

1.4.6 High oleic acid content

High oleic/low linoleic acid content in peanut seed has recently become a breeding priority worldwide. Lower linoleic acid concentrations benefit peanut processors by substantially increasing product shelf life and higher oleic acid concentrations benefit consumers by reducing blood low-density lipoprotein (LDL) cholesterol levels and increasing product flavor. The first cultivar producing a high oleic product was SunOleic 95R (Gorbet and Knaft, 1997) with seed that contained about 80% oleic acid compared to the 50% contained by most other peanut varieties at that time. A patent on the high oleic trait in peanut is held by the University of Florida (Knaft *et al.*, 2000), but for a licensing fee, the technology is available to all breeding programs. Much work has been done to reveal the genetics behind the high oleic acid trait. The two fatty acids are synthesized in the same biochemical pathway with oleic acid being the precursor to linoleic production. Moore and Knaft (1989) reported that two loci controlled the oleic/linoleic ratio in Virginia and runner-type peanuts. Lopez *et al.* (2001) determined that the inheritance of this trait is similarly controlled in Spanish market-type peanuts. Studies are underway to better understand the genetics behind the high oleic trait in peanut and to develop molecular markers linked to this trait for use in marker-assisted breeding.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

One limitation of traditional plant breeding is the lack of available genetic diversity due to the fact that only genes from within one species or

several closely related species or wild species can be utilized. As previously mentioned, cultivated peanut has very limited genetic diversity and thus an extremely limited gene pool. This narrow genetic base has created a peanut crop, which is vulnerable to damage by pests and environmental stress. Therefore, the most important tool available to traditional peanut breeders is that of hybridization. Norden (1973, 1980) noted that peanut breeders must rely on the use of introductions, hybridization, and pure line selection to produce new and improved cultivars with value-added traits.

Peanut breeders have at their disposal germplasm collections such as the US peanut collection which contains over 9000 plant accessions collected from around the world. Plant accessions in these collections include cultivated and exotic (wild) species. A plethora of genetic diversity exists among the wild *Arachis* species, the majority of which are diploid. Although hybridization between the cultivated subspecies is routinely performed, interspecific crosses in the genus *Arachis* are not easily achieved. Thus, the abundant genetic diversity available in wild species accessions is not easily moved into cultivated peanut. Singh *et al.* (1980) stated that the two major constraints to utilization of wild species are differences in ploidy level and incompatibility between some wild species and *A. hypogaea*. Successful crosses between cultivated and wild species have been reported since the 1940s but few useful cultivars have resulted from interspecific crosses (Simpson, 2001).

Another major limitation of traditional breeding is the time that is required to develop a cultivar. After the initial cross is performed, selections must be made over a period of at least six generations before replicated tests for agronomic performance can begin. Depending upon the amount of testing performed, traditional cultivar development can take from 10–20 years. Processes such as greenhouse or winter nursery use can accelerate the advancement of breeding lines, allowing for the growth of more than one generation per year. Recently, genetic linkage maps of cultivated and wild peanut species have been developed (Halward *et al.*, 1994; Burow *et al.*, 2001; Moretzshohn *et al.*, 2005) and the identification of molecular markers associated with phenotypic traits has begun (Burow *et al.*, 1996; Garcia *et al.*, 1996; Herselman *et al.*, 2004). Using current molecular techniques such as simple sequence repeat (SSR),

mirosatellite and single nucleotide polymorphism (SNP) analysis, polymorphism in cultivated peanut is being revealed (Ferguson *et al.*, 2004, 2005; Moretzshohn *et al.*, 2005). Thus, constraints to breeders due to the lack of genetic information available on peanut are quickly disappearing so that MAS breeding will become routine (Stalker and Mozingo, 2001). However, even with the use of MAS in breeding programs, traditional breeding is hindered by the number of years leading up to cultivar release.

Transgenic technology provides the means to partially overcome the limitations of traditional peanut breeding. Methods have already been developed to transform peanut via microprojectile bombardment or *Agrobacterium tumefaciens* methods (e.g., Ozias-Akins *et al.*, 1993; Schnall and Weissinger, 1993; Eapen and George, 1994; McKently *et al.*, 1995; Cheng *et al.*, 1996; Sharma and Anjaiah, 2000; Ozias-Akins and Gill, 2001). Via genetic engineering, useful genes from outside the *Arachis* genus can be inserted into and expressed in the *A. hypogaea* genome, thus overcoming the limitation of genetic diversity available using traditional methods. Many genes for disease resistance have already been transferred into cultivated peanut (Li *et al.*, 1997; Chenault *et al.*, 2002; Higgins *et al.*, 2004; Livingstone *et al.*, 2005). The second limitation of traditional breeding, time required for cultivar development, can be partially overcome using transgenic methods. Although peanut transformation has been achieved, the cultivated species is recalcitrant to the regeneration process. From beginning to end, a realistic time frame for generating a useful transgenic peanut cultivar ranges from 7 to 10 years. Although still lengthy, transgenic methods can reduce the time required for peanut cultivar development by 30–50%.

2. DEVELOPMENT OF TRANSGENIC PEANUT

2.1 Donor Genes

2.1.1 Expression of reporter and selectable marker genes

As in many of the early studies to develop efficient plant transformation systems, the first

transgenes introduced into peanut were reporter or selectable marker genes that conferred resistance to antibiotics or herbicides, and all of these genes were controlled by the constitutively expressed cauliflower mosaic virus (CaMV) 35S promoter along with the nopaline synthase (*nos*) terminator. For example, the bacterial genes coding for β -glucuronidase (GUS) (*uidA*) and neomycin phosphotransferase II (*nptII*) were stably incorporated into peanut callus (Lacorte *et al.*, 1991; Clemente *et al.*, 1992; Franklin *et al.*, 1993) (Table 3). Soon afterwards, Ozias-Akins *et al.* (1993) introduced the bacterial hygromycin resistance gene, *hph*, into peanut, this time obtaining stably transformed plants. The firefly luciferase (*luc*) reporter gene was used with peanut to monitor the transition from transient to stable expression in callus (Livingstone and Birch, 1995), as well as for aiding in selective subculturing of transgenic callus (Livingstone and Birch, 1999).

Brar *et al.* (1994) were the first to transform peanut with something other than the CaMV 35S promoter alone, introducing the *uidA* gene behind the CaMV 35S promoter followed by the alfalfa mosaic virus (AMV) 5' untranslated leader. The *bar* gene, conferring resistance to herbicides such as BASTA, was similarly constructed, but instead of the *nos* terminator, it contained the soybean rubisco small subunit terminator (Brar *et al.*, 1994). The mannopine synthase promoter was shown to be effective in driving GUS expression in leaflets from plants at the 5-leaf stage (McKently *et al.*, 1995), and Lacorte *et al.* (1997) evaluated GUS expression controlled by the 2S albumin promoter from Brazil nut and found it to be less effective than the CaMV 35S promoter. The effectiveness of monocot promoters, *Emu* and *actin 2*, also has been evaluated for their ability to express GUS transiently in peanut leaf tissue (Kim *et al.*, 1999). However, the most extensive evaluation of GUS expression driven by a heterologous promoter in peanut was performed by Wang *et al.* (1998) in which a soybean vegetative storage protein B gene (*vspB*) promoter was utilized. In this work, GUS was strongly expressed in peanut anthers, pod walls and stems, to a lesser extent in leaves, and only weakly in roots. Recently, transient expression of two fluorescent protein mutants, enhanced green fluorescent protein (EGFP) and enhanced yellow fluorescent protein (EYFP), driven by the CaMV 35S promoter have been reported, along

with production of stably transformed plants containing EGFP controlled by a double CaMV 35S plus AMV enhanced promoter sequence (Joshi *et al.*, 2005). As of the writing of this chapter, a promoter from a peanut gene has not been used to control expression of a transgene.

2.1.2 Transgenes of potential agronomic and therapeutic value

Most peanut transformation experiments have focused on introducing transgenes for increased disease resistance, particularly virus and fungal resistance. TSWV is a major pathogen of peanut. Although TSWV field-tolerant cultivars are available, no cultivars are immune. Consequently, genetic engineering for TSWV-resistant peanut has been a major thrust of several programs. The approach used has been expression of either a sense or antisense TSWV nucleocapsid (N) gene. Both Brar *et al.* (1994) and Chenault and Payton (2003) introduced an N gene from a Hawaiian TSWV isolate controlled by the CaMV 35S promoter and Nos terminator into runner cultivars important to the southeast and southwestern United States, respectively. Li *et al.* (1997) also introduced the coding region of the N gene of the Hawaiian TSWV isolate, this time behind an enhanced double CaMV 35S promoter plus the AMV 5' untranslated leader sequence along with the tumor morphology large (tml) terminator, into the Valencia market type New Mexico Valencia A. An N coding region of a lettuce isolate of TSWV (TSWV-BL) was introduced into runner cultivars Florunner, Georgia Runner, and MARC-1 (Yang *et al.*, 1998). Magbanua *et al.* (2000) is the only study to use an N gene derived from a peanut TSWV isolate, and it was introduced in the antisense orientation behind a double CaMV 35S promoter into cultivars VC1 and AT120. Other reports of transgenic peanut generated for virus resistance include the introduction into Indian cultivars of a coat protein gene of the Indian peanut clump virus (IPCVcp) driven by the CaMV 35S promoter and Nos terminator to confer resistance to clump disease (Sharma and Anjaiah, 2000) and the coat protein gene of peanut stripe virus (Higgins *et al.*, 2004).

The fungus, *A. flavus*, is an important pathogen of peanut because it produces the carcinogenic

compound, aflatoxin. It had been shown that damage to peanut caused by the lesser cornstalk borer (LCB), increases aflatoxin contamination. Consequently, to reduce injury by the LCB, and therefore subsequent *A. flavus* invasion, a *Bacillus thuringiensis cryIA(c)* gene controlled by the CaMV 35S promoter was introduced into transgenic peanut plants (Singsit *et al.*, 1997). To confer resistance to the fungal pathogen *C. arachidicola*, the causal agent of peanut leaf spot, a class I tobacco chitinase gene driven by the CaMV 35S promoter along with the selectable marker gene, *nptII*, regulated by the Nos promoter were stably expressed in plants (Rohini and Rao, 2001). *Sclerotinia* blight of peanut, caused by the fungus *S. minor* Jagger, can result in severe yield losses up to 50%. To combat this fungus, transgenics containing either a rice chitinase gene, an alfalfa B-1,3 glucanase gene (Chenault *et al.*, 2002), or a barley oxalate oxidase coding region behind a double-enhanced CaMV 35S promoter (Livingstone *et al.*, 2005) have been generated.

In all of the above studies, the introduction of a transgene was performed with the goal of improving the peanut crop. There is one report of transgenic peanut being produced, not to enhance peanut, but to use it as a means to deliver an immunogenic protein for use in oral vaccination (Khandelwal *et al.*, 2003). Rinderpest or "cattle plague" is a ruminant disease caused by an enveloped virus called rinderpest virus that produces two surface glycoproteins, one of which is hemagglutinin H. The gene encoding hemagglutinin H was cloned under the control of the CaMV 35S promoter and used to transform the cultivar TMV-2 for eventual use as a fodder to immunize animals susceptible to rinderpest.

2.2 Transformation Strategies

2.2.1 *Agrobacterium*-mediated transformation

Early attempts at developing an *Agrobacterium*-mediated transformation protocol involved infecting peanut with wild type, virulent strains. Daimon *et al.* (1990) produced transgenic hairy roots of peanut following infection with wild-type strains of *Agrobacterium rhizogenes*. However, *A. rhizogenes*-mediated transformation of peanut has

only resulted in the formation of composite plants with transformed roots on nontransformed shoots (Akasaka *et al.*, 1998).

A. tumefaciens-mediated transformation of peanut has met with more success. Lacorte *et al.* (1991) showed that strain A281 was the most virulent of the four *A. tumefaciens* strains tested on peanut, capable of inducing tumors that demonstrated both GUS and *nptII* activity on various Brazilian cultivars. Shortly thereafter, Mansur *et al.* (1993) obtained transformed calli following co-cultivation of seedling hypocotyl explants. Leaf explants have been utilized in several studies to produce transgenic plants. When leaves from young seedlings were co-cultivated with *Agrobacterium*, primary transformants were produced, however these had limited fertility (Cheng *et al.*, 1994; Eapen and George, 1994). The first reproducible *Agrobacterium*-mediated transformation protocol resulting in stably transformed and fertile transgenic peanuts was achieved when leaf section explants of New Mexico Valencia A were incubated with a tobacco leaf extract-treated strain EHA105 containing the binary vector pBI121 (Cheng *et al.*, 1996, 1997). This same group also was able to successfully introduce a TSWV N gene using the same protocol modified to obtain transgenics more quickly by reducing the concentration of selection agent in the regeneration medium (Li *et al.*, 1997). Egnin *et al.* (1998) reported that the same cultivar, New Mexico Valencia A, was more efficiently transformed by *A. tumefaciens* than the runner market types examined. Therefore, it appears that *Agrobacterium*-transformation, particularly using leaf explants, is highly genotype dependent in peanut. This fact remains the major constraint regarding *Agrobacterium* transformation of peanut.

Transformation frequencies using wounded cotyledonary node, cotyledon or hypocotyl explants from 7-day-old seedlings were compared for Indian cultivars VRI-2 and TMV-7 following co-cultivation with LBA4404 (Venkatachalam *et al.*, 1998). Following shoot bud regeneration, cotyledonary nodes were reported to be superior to the other explants with a transformation frequency of 58% when selected on 75 mg l⁻¹ kanamycin compared to 45% for hypocotyls and 40% for cotyledons (Venkatachalam *et al.*, 1998). When cultivar TMV-2 was used with the same *Agrobacterium* strain, cotyledons were

shown to be efficiently transformed following co-cultivation and subsequent somatic embryogenesis (Venkatachalam *et al.*, 2000). Cotyledon explants were also successfully used by Sharma and Anjaiah (2000). However, their protocol called for the cotyledons of JL-24 to be longitudinally bisected prior to cultivation with strain C58, followed by the promotion of adventitious bud formation.

Zygotic embryo axes of mature seeds have been used by several groups to obtain transgenics via *Agrobacterium*-mediated transformation. The first study to use these explants was McKently *et al.* (1995). Although transformants were obtained, they were largely chimeric in the T₀ generation. Mature zygotic embryos with one of the cotyledons removed of cultivar TMV-2 were precultured for 2 days before being wounded and then co-cultivated with LBA4404 that had previously been treated with tobacco wounded leaf extract (Rohini and Rao, 2000, 2001). In these studies, transformants expressing GUS (Rohini and Rao, 2000) or tobacco chitinase (Rohini and Rao, 2001) were obtained in the primary and subsequent generations tested. Precultured shoot apices obtained from embryonic axes of mature seeds of TMV-2 were inoculated with strain EHA 105 and T₀ and T₁ plants were obtained that expressed the rinderpest virus hemagglutinin H protein (Khandelwal *et al.*, 2003).

2.2.2 Microprojectile bombardment

Without question, the most widely used and genotype-independent method of transforming peanut has been through direct DNA delivery using microprojectile bombardment followed by selection on hygromycin-containing medium (Figure 2). Initially, leaflets from mature zygotic embryos were used as target tissues and transformed callus was obtained (Clemente *et al.*, 1992). However, the most successful targets for direct DNA delivery have been embryogenic cultures. This system was first reported by Ozias-Akins *et al.* (1993), and the embryogenic tissue cultures were obtained from immature zygotic embryos of the cultivars Toalson (Spanish) and Florunner (runner) isolated from seeds harvested 3–4 weeks after their pegs had penetrated the soil. This work was the first to describe transgenic peanut plants that stably expressed a transgene. Using

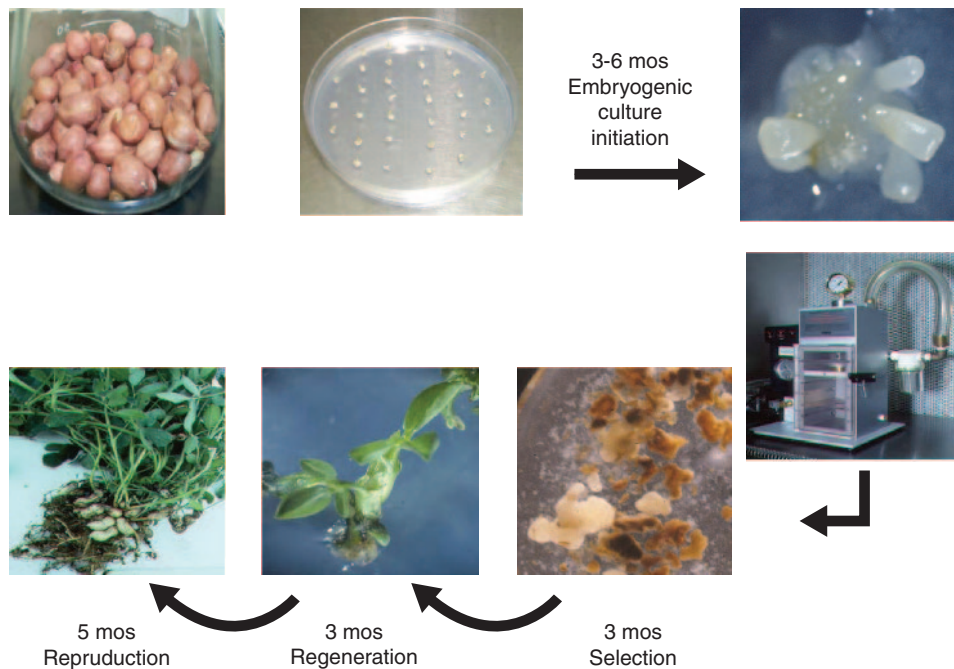

Figure 2 Steps to producing a transgenic peanut plant by the most common method, microprojectile bombardment

this system, the same group and others were able to effectively generate transgenic plants expressing *cryIA(c)* (Singsit *et al.*, 1997), GUS (Wang *et al.*, 1998), hydrolases (Chenault *et al.*, 2002), and TSWV N genes (Yang *et al.*, 1998; Chenault and Payton, 2003).

To overcome the issue of limited availability of immature seed, Livingstone and Birch (1999) produced embryogenic callus from the plumule portions of embryo axes excised from mature seeds and used those cultures as targets to introduce reporter genes into both Virginia (NC-7) and Spanish (Gajah) market types important to Australia and Indonesia, respectively. Using the same explant source, transgenic peanuts have been obtained expressing a variety of transgenes including a TSWV N gene (Magbanua *et al.*, 2000), an oxalate oxidase gene (Livingstone *et al.*, 2005), and several fluorescent reporter gene constructs (Joshi *et al.*, 2005), in a number of different market types.

The major constraint of producing transgenic peanuts via microprojectile bombardment is the amount of time involved from beginning to end. Assuming seed for embryo excision is readily

available, producing quality embryos at the correct developmental stage for bombardment requires 6–9 months. Selection in liquid and then on solid media takes another 3–4 months. Generation of shoot and root systems can take up to an additional 3–4 months. As is the case for any transgenic culture system, a major challenge can exist in maintaining sterile conditions for the period prior to soil containment. Once the T_0 plant is placed into soil and grown to maturity, another 3–4 months may be required. Conservatively, producing one generation of transgenic peanut via this method involves a minimum time period of 15–19 months.

2.3 Selection of Transformed Tissue

For *Agrobacterium*-mediated transformation of peanut, the selectable marker gene, *nptII*, has been exclusively used. Selection has been on kanamycin in the range of 50–300 mg l⁻¹. Kanamycin has been successful in these *Agrobacterium*-mediated transformation protocols because the explants used undergo shoot regeneration where kanamycin

resistance is quite effective at eliminating escapes. The only selectable marker gene used for microprojectile bombardment transformation of peanut has been *hph*, which affords recipients hygromycin resistance. Efficient selection of transformed embryogenic cultures has been with hygromycin B at concentrations of 10, 20, or 40 mg l⁻¹. While most reports have used a stepwise selection scheme (from 10 to 20 mg l⁻¹) with initial selection on liquid medium based on the protocol described by Ozias-Akins *et al.* (1993), others have used one higher concentration of hygromycin (40 mg l⁻¹) throughout the selection process until transfer to antibiotic-free medium for regeneration (Livingstone *et al.*, 2005).

2.4 Regeneration of Plants

Using *Agrobacterium*-mediated transformation methods and kanamycin selection, reported transformation rates have varied widely from 0.2% to 55%. Cheng *et al.* (1996) were able to obtain 52 transgenic plants from five independent transformation events with a transformation rate of 0.2–0.3%. Venkatachalam *et al.* (1998) reported that a 3-day preculture of explants on regeneration medium prior to *Agrobacterium* co-cultivation increased regeneration of transgenic plants. After evaluation of plants using GUS histochemical analysis and PCR, Rohini and Rao (2000) obtained a 3.3% transformation rate following an *Agrobacterium*-mediated nontissue culture protocol which called for 16 h of co-cultivation, 18 h of exposure to cefotaxime and then germination and growth for 16 days prior to transfer to the greenhouse. A transformation rate as high as 55% was reported for cotyledon explants following *Agrobacterium* inoculation with transgenic plants being rooted in approximately 120–150 days after the start of an experiment (Sharma and Anjaiah, 2000). The highest transformation rate reported thus far has been 67% with a survival rate of 90–95%. These results were obtained by Khandelwal *et al.* (2003) after preculturing shoot apices for 2 days prior to co-cultivation and selection on 100 mg l⁻¹ kanamycin.

As mentioned earlier, the first report on the regeneration of transgenic peanut plants was by Ozias-Akins *et al.* (1993). In that study, approximately 1% of the embryogenic calluses

bombarded and selected for hygromycin resistance yielded a stably transformed cell line, and 100 primary transformants were obtained in total. Brar *et al.* (1994) were able to recover only 11 primary transgenics following bombardment of 800 shoot meristems of embryonic axes following screening for GUS activity. In the method described by Livingstone and Birch (1999), three to six independent transformants per bombardment of embryogenic callus could be obtained, and this level of recovery appears to now be standard when using hygromycin as the selection agent. Recently, Livingstone *et al.* (2005) obtained 200 primary transgenic plants from three cultivars following this transformation and selection scheme, while another report on the use of fluorescent reporter genes for visual selection of transformed peanut plants resulted in a low level of transformation, with less than one line obtained per bombardment (Joshi *et al.*, 2005).

2.5 Testing of Transgenic Peanuts

As is the case with other plants, peanut transgenics obtained via *Agrobacterium*-mediated transformation tend to have single or low copy number insertions with progeny segregating in a 3:1 ratio (Cheng *et al.*, 1997; Sharma and Anjaiah, 2000; Rohini and Rao, 2001), whereas those obtained from microprojectile bombardment tend to have variable copy number and can exhibit a variety of rearrangements as evidenced by Southern blot analysis (Ozias-Akins *et al.*, 1993; Yang *et al.*, 1998). Additionally, primary peanut transformants can have reduced fertility and lower yields than their nontransformed controls. Rohini and Rao (2001) reported that T₀ plants expressing tobacco chitinase grew more slowly when compared to nontransformed controls. Also, T₀ plants expressing oxalate oxidase did not have vigorous growth and their fertility was variable, but these results were not correlated with expression of the transgene. Normal growth was restored in the T₁ generation (Livingstone *et al.*, 2005). Particularly when embryogenic cultures are used for transformation, the culture period prior to bombardment should be short to increase the chances of obtaining fertile plants. Livingstone and Birch (1999) recommend using callus cultures that are less than 9 months old to increase fertility.

Unfortunately, the minimum time required to generate embryos useful for bombardment is 6–9 months.

Molecular characterization of T_1 lines has shown stable integration and high levels of gene expression for a number of transgenes. These transgenes have shown efficacy against target insects like the LCB (Singsit *et al.*, 1997), viruses such as TSWV (Magbanua *et al.*, 2000), and fungi, particularly *S. minor* (Chenault *et al.*, 2003; Livingstone *et al.*, 2005). Peanut transformation has developed into an effective strategy to improve the crop.

2.6 Regulatory Measures

To date, no transgenic peanut cultivar has been released for commercial production. Genetic modification of organisms is feared by the general public, especially when the end product is one of food for human consumption, resulting in the development of a network of regulatory systems around the world. The cost of meeting such regulatory requirements for globally traded crops is estimated at \$20–\$30 million per product (McElroy, 2003) which has limited the release and production of transgenic crops to large multinational corporations. Most regulatory agencies focus on the specific DNA construct involved in the transformation rather than the beneficial trait itself, a fact widely debated by those in the scientific community (Bradford *et al.*, 2005; Parrott, 2005; Ponti, 2005).

A risk-based strategy has been proposed for regulating transgenic crops, breaking them down into classes based upon true risks associated with gene function and based on scientific criteria (Barton *et al.*, 1997; Strauss, 2003). Following this strategy, *low risk* crops include those where the transgene involved imparts a trait which is functionally equivalent to that manipulated by traditional breeding and no novel biochemical functions are manipulated (i.e., changes in homologous gene expression achieve a commercially useful trait). The *moderate risk* category involves crops producing plant-made pharmaceutical proteins, that have very low human and environmental toxicity or nonfood crops that have low nontarget ecological impact. Those transgenic crops at *high risk* include

those producing transgene products that have a documented likelihood to cause significant harm to humans, herbivores, or the environment.

In the United States, laws currently used to regulate transgenic products are the Plant Protection Act (PPA), the Federal Food, Drug, and Cosmetic Act (FFDCA), the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), and the Toxic Substances Control Act (TSCA). The current system in place in the United States involves three government agencies (<http://www.usbiotechreg.nbii.gov>), each with a specific role in regulation. The USDA-ARS Animal and Plant Health Inspection Service (USDA-ARS APHIS) controls the entire development of the transgenic crop until nonregulated status is granted because nonpest status has been shown. USDA-APHIS also regulates the transportation, importation, field testing, and disposal of all transgenic plants. The Environmental Protection Agency (EPA) regulated the distribution and sale, use, and testing of any pesticidal substance, including transgenic crops. The Federal Drug Agency (FDA) serves to ensure that plant-derived foods or drugs are properly labeled for consumer use.

Although adoption of transgenic crops has rapidly progressed in the United States, Argentina, and Canada (Ponti, 2005), the general public in Europe still resists their importation and use. This adversity is believed to be based on consumer concerns regarding the safety of transgenic crops with regards to long term effects on the human population and the environment. Much debate continues on the utility of transgenic crops considering the quasi moratorium placed on transgenic products in the European Union (EU).

3. FUTURE ROADMAP

3.1 Expected Products

3.1.1 Disease resistance

3.1.1.1 Fungal resistance

Much of the crop improvement using transgenes in peanut has been directed toward disease resistance. This is the typical trend for first-generation transgenic crops. Clearly significant

economic benefit can be gained by the growers when host resistance to pests and diseases is available. When host resistance reduces pesticide input, a significant benefit to the environment also would be anticipated as a consequence. Chemical input to control leaf spot disease is costly. In Georgia alone, the cost of control for 2005 was estimated to be approximately \$36 million, which involved primarily the cost of fungicide application (Kemerait, 2006). Host plant resistance would reduce both costs of production and chemical release into the environment. The consumer does not typically embrace a transgenic crop when its primary benefit is to the economic well being of the grower. The simultaneous benefits of reduced chemical use to the environment and consumer exposure often are overlooked but should be an important consideration for deregulation of transgenic crops.

Fungal resistance is a phenotype category for which there are no crops yet deregulated by USDA-APHIS in the United States, or corresponding regulatory agencies in other countries (database of genetically modified organisms (GMOs) deregulated in the United States at <http://www.isb.vt.edu> and biotech crop database at <http://www.agbios.com/main.php>), in spite of the fact that more than 700 field trials have been conducted for putative fungal resistance in the United States alone (database of US field tests of GMOs at <http://www.isb.vt.edu>). The slow release of fungal-resistant transgenic cultivars may be due to a number of factors but probably is largely associated with the economics of targeting only one or a few pathogens per transgene combined with incomplete efficacy. Deregulation has become a costly endeavor and can be justified

at this time only for major effect genes. As previously discussed, multiple federal agencies typically are involved in the process of deregulation through a coordinated framework (<http://www.usbiotechreg.nbii.gov/index.asp>), which extends the time and costs associated with product approval. Nevertheless, given the intensive use of fungicides in peanut, the greatest impact on peanut production and a safer environment could be achieved with fungal-resistant cultivars.

Genes that currently are being explored to achieve fungal resistance potentially can target one or more of the following pathogens including, *S. minor*, white mold (*S. rolfsii*), early and late leaf spot (*C. arachidicola* and *C. personatum*, respectively), and *Aspergillus flavus/parasiticus* (Table 4). None of these are classical R genes that would act in a gene-for-gene resistance scenario (Dangl and McDowell, 2006), but rather are acting downstream in some part of the inducible or constitutive host resistance pathway. There are many such genes that could act to inhibit fungal growth or invasion or to activate further plant defense responses (Punja, 2001), but the resistance achieved typically is incomplete. A broad-spectrum antimicrobial gene potentially would have the greatest economic impact by conferring disease resistance to multiple pathogens; however, it might also have the greatest potential to disturb the beneficial symbiotic relationship between peanut and *Rhizobium*, a bacterium. The *Rhizobium*-legume symbiosis benefits the plant by providing a source of fixed nitrogen and reduces the cost and pollution potential of inorganic nitrogen application. Genes that are in various phases of research and development are listed in Table 4.

Table 4 Putative antifungal genes engineered into peanut

Genes of interest	Gene sources	Pathogens target	References
Chitinase	Tobacco	<i>Cercospora arachidicola</i>	Rohini and Rao, 2001
Chitinase	Rice	<i>Sclerotinia minor</i>	Chenault <i>et al.</i> , 2005
		<i>Aspergillus flavus</i>	Chenault <i>et al.</i> , 2004
β -glucuronidase	Alfalfa	<i>Sclerotinia minor</i>	Chenault <i>et al.</i> , 2005
		<i>Aspergillus flavus</i>	Chenault <i>et al.</i> , 2004
Oxalate oxidase	Barley	<i>Sclerotinia minor</i>	Livingstone <i>et al.</i> , 2005
Chloroperoxidase	<i>Pseudomonas pyrocinia</i>	<i>Aspergillus flavus</i>	Niu <i>et al.</i> , 2004
Lytic peptides	D4E1	<i>Aspergillus flavus</i>	Weissinger <i>et al.</i> , 2001
Ribosome inactivating protein	<i>Zea mays</i>	<i>Aspergillus flavus</i>	Weissinger <i>et al.</i> , 2004
Bcl-xl	Human	<i>Aspergillus flavus</i>	Chu <i>et al.</i> , 2005

3.1.1.2 Virus resistance

Virus diseases also cause significant losses to the peanut industry. In the United States, the viral disease of most concern is tomato spotted wilt, a tospovirus disease that is vectored by thrips. Crop losses due to viral infection approach the value of fungal disease control (Kemerait, 2006). There is no chemical control for TSWV although there are management strategies, the most important being host plant resistance (<http://www.sacs.cpes.peachnet.edu/spotwilt>). Host plant resistance has been enhanced with pathogen-derived resistance where a gene from the virus, when expressed in the host plant, can confer resistance to the virus from which the gene originated and sometimes related viruses (Beachy, 1997). This approach has been explored in peanut where the N protein gene from TSWV, in sense or antisense orientation, was constitutively expressed in the plant (Li *et al.*, 1997; Yang *et al.*, 1998; Magbanua *et al.*, 2000), and one line expressing protein was shown to have elevated levels of resistance over multiple years of field testing (Yang *et al.*, 2004). The costs of deregulation and freedom to operate have been prohibitive for further development of this transgenic line as a commercial cultivar. Future approaches in peanut could exploit the RNA silencing/RNA interference (RNAi) pathway in plants whereby any viral gene could be targeted for degradation by introducing an inverted repeat of part the gene into the host genome (Helliwell and Waterhouse, 2003; Dunoyer and Voinnet, 2005). Homology dependent gene silencing should operate in most transgenic lines unless the virus has a suppressor of silencing that functions within the same pathway (Goldbach *et al.*, 2003; Moissiard and Voinnet, 2004). Viruses other than TSWV are of minor concern in the United States. However, in Africa, India, or Southeast Asia, groundnut rosette, peanut clump, and peanut stripe can be serious diseases in addition to tospovirus diseases. Transgenic lines expressing a peanut clump virus coat protein gene (Sharma and Anjaiah, 2000) or a peanut stripe coat protein gene sequence (Higgins *et al.*, 2004) have been produced and hold promise for virus resistance in peanut, particularly in developing countries where a more favorable environment for release of GMOs may exist.

3.1.2 Pest resistance

3.1.2.1 Insect resistance

Insect pests are sporadic problems on peanut and most can be effectively managed with curative rather than preventative sprays (Funderburk and Brandenburg, 1995). Many of these insect pests are foliage feeders. One notable exception is the LCB, typically a pod feeder. LCB can scarify or penetrate pods when feeding and thereby increase the vulnerability of peanut to invasion by *A. flavus/parasiticus*. Both of these fungi produce the carcinogenic mycotoxin, aflatoxin, which is a frequent contaminant of peanuts, corn, cottonseed, and some tree nuts grown under drought stress. Toxin levels are strictly controlled in the United States but not in developing countries where acute aflatoxicosis in humans and animals has been recently observed. Aflatoxin levels in seeds of peanut have been consistently correlated with insect-damaged pods (Lynch and Wilson, 1991). Insect resistance genes in peanut germplasm have not been extensively surveyed although some have been identified (Stalker and Simpson, 1995). One future strategy might be to introduce resistance genes from outside of the genus. Insect resistance in transgenic plants has been achieved primarily through the introduction of insecticidal crystalline protein genes from the soil bacterium, *Bacillus thuringiensis* (*Bt*) (Christou *et al.*, 2006). *Bt* toxins are considered to be highly selective for the target pest species with no direct detrimental effect on nontarget beneficial insects, although there can be an expected indirect effect due to prey availability or quality (Romeis *et al.*, 2006). The *Bt* toxin, *cryIA(c)*, was shown to effectively reduce feeding of LCB on foliage and pods of peanut when the protein was constitutively expressed in the plant (Singsit *et al.*, 1997; Ozias-Akins *et al.*, 2002). In spite of *Bt* toxin efficacy, freedom to operate with *Bt* genes was in litigation at the time the initial *Bt*-peanut research was conducted and resolution was not encouraging for peanut. In addition, the widespread adoption of *Bt* cotton across the peanut belt precluded the release of *Bt* peanut for resistance management reasons. The concern is that continuous exposure of an insect pest to a single *Bt* toxin will select for toxin-resistant insect populations (Tabashnik,

1994). One resistance management strategy is the planting of nontransgenic refugia next to fields of transgenic crops (Gould, 1998). A second strategy is to introduce multiple *Bt* toxin genes, some of which have different modes of action. A “stacked” resistance with more than one *Bt* gene is considered a better approach to reduce the probability that insects will become resistant to the plant-expressed protein. Monsanto has followed this approach in their development of YieldGard[®] Plus corn where genes for two different *Bt* toxins (Cry3Bb1 and Cry1Ab) were combined as plant-incorporated protectants to confer resistance to European corn borer and corn rootworms (http://www.epa.gov/pesticides/biopesticides/ingredients/factsheets/factsheet_006430-006484.htm). Although other insect resistance genes have been identified, such as cowpea trypsin inhibitor (Hilder *et al.*, 1987), none are as effective or selective as *Bt* toxin genes (Christou *et al.*, 2006). However, the combination of cowpea trypsin inhibitor and *Bt* toxin genes has shown additive effects in some species and antagonism in others (Oppert, 1999). The combination of *Bt* and a native resistance gene in soybean is more effective than either alone (Walker *et al.*, 2004) and the same is true in potato (Westedt *et al.*, 1998).

3.1.2.2 Nematode resistance

The main nematode pest in peanut is the root-knot nematode, *M. arenaria*. As discussed earlier, a high level of resistance has been found in several of the wild diploid relatives of peanut (Holbrook and Noe, 1990) and that resistance has been introgressed into cultivated peanut through interspecific hybrids (Simpson and Starr, 2001; Simpson *et al.*, 2003). The released cultivars were developed for the southwestern United States where TSWV is not a problem on peanut; therefore, further cultivar development to combine nematode with TSWV resistance in genotypes adapted to the southeastern United States is in progress. Cultivar development for the nematode resistance trait is being facilitated by MAS (Chu *et al.*, 2006). Given that most nematode resistance (R) genes cloned to date are in the NBS-LRR class of R genes, it is possible that a resistance gene analog (Bertioli *et al.*, 2003; Yuksel *et al.*, 2005) for nematode resistance could be cloned

from *Arachis* spp. and engineered into cultivated genotypes. The choice to pursue this genetically modified (GM) alternative to traditional breeding would depend on the economics of the situation. A particularly intriguing mechanism of resistance to root-knot nematode is the use of the RNA silencing mechanism in plants to knockdown a signaling pathway that is required for the nematode to communicate giant cell formation by the plant (Huang *et al.*, 2006). Stacked resistance where the pest would encounter mechanistically different defense strategies is always preferable when it can be achieved because it will reduce the likelihood for the pest to evolve resistance.

3.1.3 Abiotic stress tolerance

3.1.3.1 Drought tolerance

The most significant abiotic stress for peanut is drought, not only because of the direct effect on plant productivity, but also because of the indirect effect on aflatoxin production. A plant under stress apparently stimulates infecting *Aspergillus* fungi to synthesize aflatoxin. Irrigation is an effective management tool for aflatoxin reduction; however, it is not always feasible. Drought-tolerant peanut genotypes have been shown to be less susceptible to aflatoxin production than drought-sensitive genotypes (Holbrook *et al.*, 2000a). The genetic component for drought tolerance is complex and transgenic technologies might provide an alternative route for enhancing drought tolerance. Abiotic stresses commonly result in osmotic and oxidative stress and strategies to mitigate the associated cellular damage can lead to stress tolerance (Wang *et al.*, 2003). The most effective approaches up to now involve the manipulation of signaling pathways or the up-regulation of structural protectants such as osmolytes or antioxidants that can confer some degree of tolerance. One component of drought stress signaling is phospholipase D (PLD), an enzyme that hydrolyzes phospholipids to produce phosphatidic acid. In peanut, PLD is more highly expressed in response to drought in drought-susceptible cultivars (Guo *et al.*, 2006). Its expression may contribute to phospholipid membrane breakdown; therefore, its suppression could promote drought tolerance.

3.1.3.2 Herbicide tolerance

Since chemical stress is a component of abiotic stress, herbicide tolerance falls in this category. Herbicide tolerance is the most popular genetically engineered trait in deregulated crops (James, 2005). Roundup Ready (glyphosate tolerant) cotton and soybean have been developed and are widely grown in the United States. Since peanut typically is grown in rotation with cotton, it would not be ecologically sound to release glyphosate-tolerant peanut. Weeds resistant to this herbicide (e.g., pigweed) already can be a serious problem for cotton cultivation. There are numerous weed pests in peanut, and preplant and pre or postemergence chemical control is an important component of weed management (Brecke, 1995). A broad spectrum of herbicides is registered for use on peanut. Herbicide resistance genes other than EPSPS (for glyphosate resistance) have been identified (Duke, 2005) and could be engineered into peanut, provided that the chemical company with ownership of the herbicide would consider registration for use on peanut to be an economically feasible endeavor. These costs would be in addition to the costs of deregulating the transgenic crop.

3.1.4 Product quality

3.1.4.1 Oil composition

Peanut is classified as an oilseed crop because the seeds are rich in oil (~50%). In the United States, however, a premium price is paid for confectionary quality peanuts and the price for oilstock peanuts is relatively low. Oil composition of the peanut seed affects end quality for both oil and confectionary items. A high ratio of oleic to linoleic acid (high-OL) is desirable for prolonged shelf life and reduced rancidity of oils (<http://www.foodproductdesign.com/archive/2000/0500pp.html>). Since a ratio of 40:1 oleic to linoleic acid has been achieved in spontaneous mutants of the δ -12-oleoyl desaturase genes in peanut (Moore, 1999; Knauff *et al.*, 2000), it is less likely that a transgenic approach would be used for the purpose of high-OL in peanut even though the relevant desaturase genes have been characterized (Jung *et al.*, 2000).

As is the case for most other oilseed crops, peanut could be engineered to produce specialty or industrial oils (Dyer and Mullen, 2005; Murphy, 2006; Scarth and Tang, 2006) if the industry were committed to segregating the crop and preserving identity to the end use. The economy of specialty oil production in peanut versus other commodities (soybean, cottonseed, rapeseed/canola, sunflower, palm, corn) also would have to be taken into account. The potential of designer oil crops has not been realized in part due to the complexity of fatty acid biosynthesis, cellular compartmentalization of novel fatty acids, and insufficient yields for economic viability (Murphy, 2006).

The ω -3 fatty acids reduce risk of coronary heart disease and fatty fish serve as a major source of this nutrient. Land-based plant sources are being proposed although currently the main ω -3 fatty acid in plants, α -linolenic acid (18:3), is undesirable in oils because of its susceptibility to oxidation. Most oilseeds are being developed to produce more stable oils that contain high levels of monounsaturated fats such as oleic acid (18:1), which also have health benefits. The most effective forms of dietary ω -3 fatty acids are fish-derived eicosapentaenoic and docosahexaenoic acids, and the α -linolenic to eicosapentaenoic intermediate stearidonic acid (18:4) has been proposed for increasing the bioconversion efficiency of plant-derived ω -3 fatty acids (Ursin, 2003). Further proof of concept for manipulation of ω -3 fatty acid content in foods would be more efficiently done in species that are easier to transform than peanut (Zhang *et al.*, 2005), and the most feasible strategy subsequently could be adopted for peanut.

Peanut oil was the original oil proposed for the manufacture of biodiesel by Rudolf Diesel (<http://www.cyberlipid.org/glycer/biodiesel.htm>). The current cost of peanut production using management practices that will yield a large and high-quality crop for human consumption likely would be prohibitive for biodiesel purposes. In Georgia, the cost of peanut oil exceeds that of corn, soybean, or rapeseed (<http://www.agecon.uga.edu/~caed/biodieslrpt.pdf>). However, peanut cultivars that have reasonable yields with minimal input probably could be developed with a combination of traditional breeding and GM technologies. These cultivars would need to incorporate drought tolerance for dryland production and multiple resistances for host plant

rather than chemical control of diseases and pests. Additionally, the oil content of peanut is known to vary among genotypes (Isleib *et al.*, 2004) and the trait for high oil production could be manipulated either through traditional breeding and selection or using transgenic technologies (Dyer and McMullen, 2005).

3.1.4.2 Proteins

Peanut fruit, although botanically a legume, not a nut, contains proteins that cause allergic reactions in humans of the same order of magnitude as several tree nuts (Sicherer *et al.*, 1998). The majority of the allergic reactions to peanut can be attributed to three seed storage proteins, Ara h 1 (vicillin), Ara h 2 (conglutin), and Ara h 3 (glycinin). Ara h 1 also is known as conarachin and Ara h 3 as arachin. There has been considerable debate regarding the value of searching for genotypes naturally devoid of one or more of these allergens or of suppressing the levels of one or more allergens through gene silencing (Ozias-Akins *et al.*, 2006). Since all three allergens are seed storage proteins, they have a function in the support of seed germination and seedling development. To what extent the absence of one or more of these three proteins would affect seed viability or peanut flavor is not yet known. There is precedent, however, for eliminating seed storage proteins in other crops through the discovery of natural variation (Burow *et al.*, 1993; Joseph *et al.*, 2006), or gene silencing (Herman, 2005). Since peanut is a relatively recent polyploid, and has undergone an evolutionary bottleneck (Kochert *et al.*, 1996), the probability to discover natural allergen-free variants within the cultivated species is low. Screening for induced mutations is one non-GM strategy (Ozias-Akins *et al.*, 2006). The GM strategy, allergen gene silencing using RNAi, might eventually gain consumer acceptance if the silencing were shown to be stable, but in the interim silencing through RNAi is a valuable means to test the effect of altering protein composition of the seed on seed viability. Seeds with altered protein content also could be tested for allergen sensitization and reaction in animal models such as mouse and pig (Li *et al.*, 2000; Helm *et al.*, 2002). The allergen, Ara h 2, also has been shown to

possess trypsin inhibitor activity (Maleki *et al.*, 2003) and trypsin inhibitors are reported to have insecticidal or antifungal activities (Gatehouse and Gatehouse, 1998; Chen *et al.*, 1999). A possible negative consequence of reducing such an allergen could be increased susceptibility to pests or pathogens. Conversely, a consequence of engineering enhanced pest or pathogen resistance could be increased allergenicity. This consequence should be considered on a case-by-case basis depending on the protein gene that would be introduced.

Legume proteins are deficient in methionine, hence vegetarian diets include a balance of cereals with legumes to obtain essential amino acids. Peanut seeds consist of approximately 25% protein, the majority of which is arachin and conarachin, or 11S and 7S globulins, respectively. A methionine-rich protein has been identified in peanut (Mazhar and Basha, 2004), and it is conceivable that its content could be increased through genetic engineering. Other means for improving protein quality include transformation with a synthetic peptide gene that encodes incorporation of essential amino acids (Jaynes and Derrick, 1998; Beauregard and Hefford, 2006). Scenarios for enhancing the sulfur-containing amino acids in soybean have been proposed and would be applicable to peanut (Krishnan, 2005). Protein quality goals may differ for edible peanuts versus oilcake protein destined for animal feed.

3.1.4.3 Vitamins and other bioactive compounds

Peanut seeds are naturally high in vitamin E and folate (McKevith, 2005), and their consumption by peanut-tolerant individuals is recommended as part of a folate-rich diet during pregnancy (<http://www.marchofdimes.com/professionals/14332.1819.asp>). Folate is known to reduce the chance of neural tube defects, one consequence of which is spina bifida. Metabolic engineering for increased folate has not yet been attempted in peanut and so far has been able to achieve only modest increases in other plants (Rebeille *et al.*, 2006). Folate metabolism in plants is complex but now well characterized with different parts of the biosynthetic pathway being housed in different subcellular compartments (chloroplasts,

mitochondria, cytosol) (Basset *et al.*, 2005). There is considerable flux in folate levels during growth and development due to its importance to multiple biochemical pathways and more than one rate-limiting step in its biosynthesis. Although it may be premature to attempt the enhancement of folates in peanut, the natural ability to produce significant levels of folate in the peanut seed may predispose this crop to successful engineering of even higher folate levels.

Vitamin E is a collective term for several tocopherol and tocotrienol compounds and is an essential component of mammalian diets. The highest vitamin E activity can be found in α -tocopherol, and vitamin E is partitioned into the oil fraction that is extracted from oilseeds. Vegetable oils are an important source of vitamin E in the human diet. Vitamin E biosynthesis has been genetically well characterized in the model dicot, *Arabidopsis thaliana*, and facilitated by earlier genetic and biochemical analyses in the cyanobacterium, *Synechocystis* (DellaPenna and Last, 2006). Engineering of the oilseed, soybean, to increase vitamin E activity fivefold, but not the total tocopherol content, was accomplished by the combined overexpression of two enzymes in the biosynthetic pathway. These were VTE3 which is unique to the γ - and α -tocopherol branch of the pathway and VTE4 which catalyzes the last step in converting γ - to α -tocopherol or δ - to β -tocopherol (Van Eenennaam *et al.*, 2003; Sattler *et al.*, 2004). Peanut seeds already have a considerably higher α -tocopherol content than soybean, but perhaps a similar strategy could enhance the vitamin E activity of peanut.

Polyphenols include secondary metabolites such as some phytoalexins and flavonoids among other substances. Their roles in plants and human health are multifunctional (Parr and Bolwell, 2000). Engineering their composition could fortify functional foods, but since they also play a role in plant defense, the opportunity exists to benefit the plant as well (Treutter, 2006). Some specific goals for peanut might be to alter the quantity or distribution of resveratrol or insecticidal flavonoids. Resveratrol is a stilbene phytoalexin that also is prevalent in grapes and may be responsible for one of the health benefits of red wine (Cordova *et al.*, 2005). Resveratrol was implicated in protecting peanut seeds from *Aspergillus* growth (Wotton and

Strange, 1987), and was negatively correlated with disease incidence in transgenic tobacco expressing a heterologous stilbene synthase gene (Hain *et al.*, 1993). A secondary product that reduces aflatoxin formation by *Aspergillus* is gallic acid, a component of hydrolysable tannins in seed coats of certain walnut cultivars (Mahoney and Molyneux, 2004). Insecticidal effects have been attributed to the flavonoids quercetin and rutin that are present in the foliage of a wild peanut species but not cultivated peanut (Mallikarjuna *et al.*, 2004). The potential for modifying phytoalexins and flavonoids for dual benefit is broad but complex.

3.1.4.4 Therapeutics

Peanut could serve as a vehicle for the manufacture of protein therapeutics just as many other crop commodities (Vitale and Pedrazzini, 2005). The primary issue for crop choice for plant-made pharmaceuticals is the chance for mixture with product intended for human consumption (Horn *et al.*, 2004; Ma *et al.*, 2005). Maize has been promoted for plant-made pharmaceuticals although the growth of transgenic therapeutic-producing genotypes in high corn production areas is not considered by many to be an acceptable scenario because the risk for contamination of maize grown for feed or food would be too great. Peanut seeds contain abundant (~25%) protein and likely would be suitable for the production and extraction of therapeutic proteins, although if cultivated in close proximity to other cultivars, some risk of contaminating other crop sectors would be encountered as with corn. With peanut, the risk would be primarily through seed mixture rather than cross-pollination.

In regions where peanut may be grown for animal fodder, the possibility exists to engineer protein production for animal vaccination. The rinderpest virus causes serious disease in wild and domesticated ruminants. As previously noted, oral immunization is being attempted through the expression of the hemagglutinin protein of rinderpest virus in peanut (Khandelwal *et al.*, 2003).

3.2 Risks and Concerns

The main impediments to the use of transgenic peanut in the commercial arena are the negative

sentiment toward transgenic crops in general in the EU (Ponti, 2005), a major export market for peanut, and the costs associated with deregulation and freedom to operate. Peanut is a subtropical crop and is not a major crop in many developed countries; therefore, less funding has been available for its improvement.

Cultivated peanut is tetraploid and its wild relatives are primarily diploid. Peanut also is a self-pollinated crop. Crosses between diploids and tetraploids have not been documented in nature. There is a low risk of transgene escape into the environment because of peanut's pollination biology and with the exception of South America where peanut is endemic, its lack of tetraploid congeners. Only domesticated forms of peanut are widespread in the southern United States, and they do not compete in the wild over multiple generations. A similar pattern would be expected in other regions of the world where environmental conditions would not be favorable for persistence.

The potential negative ecological or health impacts of traits introduced into peanut would rarely be unique to the crop. On the contrary, the low risk of transgene escape compared with many other crops would be more favorable for peanut. The same issues of pest resistance to plant-incorporated pesticides or antifungals would plague peanut along with other crops and are best resolved on a trait-by-trait or gene-by-gene basis rather than by commodity. Interestingly, liability for impeding the release or adoption by industry of a transgenic plant that would have a health benefit has been discussed as a likely scenario counter to the current trend of not accepting transgenic plants because of unknown risks (Miller *et al.*, 2006).

3.3 Expected Technologies

While peanut transformation is reproducible, it still is low in efficiency and more research to improve the efficiency would be justified, particularly as a functional genomics tool. While hygromycin resistance is a very effective selection method for peanut, there is a trend to eliminate antibiotic resistance genes from the plant transformation toolbox. Alternative selectable marker genes have been proposed and tested in other plants (Miki and McHugh, 2004), but their effectiveness in peanut remains to be examined. The promoter toolbox

available for dicots also provides a resource for peanut. There may be instances where the cost of constitutively expressing a defense protein, for example, is too great to plant productivity. Targeted expression by manipulating regulatory regions is feasible and likely to be more extensively implemented in the future.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Flax (*Linum usitatissimum* L.) is an annual, self-fertilizing plant grown either for its fiber (flax, fiber flax) or for its seed oil (oilseed flax, seed flax, linseed). The species is believed to have originated in either the Middle East or Indian regions (Vavilov, 1951; Durrant, 1976) and spread throughout Asia and Europe, prior to its introduction into the New World. Flax was one of the first crops domesticated by Man around 7000 BC, and archaeological evidence shows the presence of seeds of its wild progenitor *Linum bienne* in human habitats as long ago as 8000 BC (van Zeist and Bakker-Heeres, 1975). Utilization of both the stem fiber and the seed oil can be traced back to early civilization in Egypt and the Middle East, where linen (the fabric made from flax fiber) was worn as clothing and used to wrap mummies, and the seed oil was used in embalming (Durrant, 1976).

Flax is widely adapted to temperate climates of the world, although a degree of regional specialization has occurred. Fiber flax cultivars are taller and less branched and are grown in cool-temperate regions throughout the northern hemisphere, especially in North Asia and eastern Europe. Fiber flax remained the principal vegetable fiber in western nations throughout history until the beginning of the last century when cotton took its place. Nowadays fiber flax

is cultivated on approximately 500 000 hectares worldwide, principally in China, the Russian Federation, and Western Europe (Table 1). Annual global production of around 860 000 tons of fiber accounts for only 3% of the 25 million tons global supply of plant fiber and makes flax now only the third most important plant fiber behind cotton and jute. Linseed cultivars are shorter, more branched, and larger seeded and are grown over a wider area in warmer regions such as Canada, India, China, United States, and Argentina. Linseed is currently cultivated on over 3 million hectares worldwide, producing about 3 million tons of seed (Table 1). This represents a 50% decline compared to the 6 million hectares that linseed was grown on in the early 1970s. The oil equivalent of current production is around 1 million tons, which is around 1% of total world vegetable oil production.

1.2 Economic Products

Flax fiber is obtained from the fibrous bundles, primarily composed of cellulose, that run the full length of the tall fiber flax stem. The individual fiber cells range up to 4 cm in length and are organized as bundles of overlapping strands. Flax fiber is released by a process known as retting and is stronger, more durable, and more moisture absorbent than cotton or wool. The best grades are used for linen fabrics such as damasks, lace, and sheeting. Coarser grades are used for the manufacturing of twine and rope. The stems of

Table 1 Area and production for the top five fiber flax and linseed flax producing countries and world totals for the year 2005^(a)

Crop type	Country	Area (hectares)	Production (tons)
Fiber flax	China	161 000	470 500
	Russian Federation	89 210	55 890
	France	78 644	90 000
	Belarus	71 000	50 000
	Ukraine	23 600	12 700
	Other countries	82 318	180 353
	World total	505 772	859 443
Linseed flax	Canada	803 000	1 082 000
	India	636 000	230 000
	China	570 000	480 000
	USA	386 480	500 280
	Ethiopia	215 000	125 907
	Other countries	502 869	440 231
	World total	3 113 349	2 858 418

^(a) Source: FAOSTAT (<http://faostat.fao.org/site/340/default.aspx>)

the shorter oilseed flax types are also sometimes processed for fiber, especially for use in the high quality paper industry such as in banknotes and cigarettes papers where they provide a combination of high strength and light weight.

In the late 19th and early 20th centuries the decline in fiber flax cultivation was paralleled by increasing cultivation of linseed as an industrial oilseed crop. Industrial uses for linseed oil are based on its high content (>50%) of α -linolenic acid (9,12,15-octadecatrienoic acid). The polyunsaturated nature of linolenic acid imparts a high susceptibility to oxidation and polymerization, making it a valuable drying agent for use in paints, inks and other surface coatings, and as the main ingredient of linoleum. Industrial use of linseed oil peaked during the 1960s when oil-based paints predominated. However, the development of synthetic products from the petrochemical industry resulted in a shift to acrylic paints and vinyl floor coverings, and a consequent decline in demand for linseed oil for industrial purposes. This decline has stabilized somewhat recently with a renewal of interest in natural products and increasing concern over the level of volatile organic compounds released from synthetic coatings.

α -linolenic acid is also an essential fatty acid in the human diet and belongs to the ω -3 group of fatty acids that are increasingly being recognized

as having beneficial effects on a range of health and well-being concerns (Simopoulos, 2003). However, its oxidative instability severely restricts the use of extracted linseed oil in food products and cooking applications. As a result, human consumption of linseed oil has mainly been as a dietary supplement protected from oxidation either by encapsulation or by storage under nitrogen in small volume bottles. Whole linseed grain has also increased in popularity as a means to obtain α -linolenic acid in a more naturally protected form. It is used in a range of wholegrain products, such as multigrain breads, muesli, and breakfast cereal toppings. Ground flaxseed is also used as component in breads (Pohjanheimo *et al.*, 2006). Consumption of the whole seed or ground seed has an added nutritional benefit because it is one of the richest sources of lignans, compounds that have been shown to have strong anticancer properties (Westcott and Muir, 2003).

Recently, a modified form of linseed oil that is very low in linolenic acid was developed by plant breeding to expand the opportunities for the oil in the food industry (Green and Dribnenki, 1994). The new form, called LinolaTM (LinolaTM is a registered trademark of CSIRO, Australia), is similar in composition to sunflower and safflower oils and its considerably improved stability compared to conventional linseed oil, has enabled it to be used successfully in margarines and salad oils.

The meal remaining after extraction of oil from the seed contains about 33% protein and is commonly used as an animal feed, especially for ruminant animals such as cattle and horses. Although the meal can be used for nonruminant animals, such as pigs and poultry, the maximum inclusion levels are relatively low due to its high content of indigestible mucilage and the presence of linatine, an antinutritional factor that inhibits vitamin B6.

1.3 Taxonomy, Cytogenetics, and Genomics

The *Linum* genus belongs to the family Linaceae and has been divided into five sections (*Linum*, *Dasylinum*, *Cathartolinum*, *Linastrum* and *Syllinum*) based on chromosome number, cytology, and floral morphology (Nagao, 1941; Simmonds, 1976). *L. usitatissimum*, along with its proposed progenitors *L. angustifolium* and *L. bienne*, belongs to the section *Linum*, a grouping

of species that is distinguished from the other four sections by having homostylous rather than heterostylous flowers. Comparisons of *Linum* species for fatty acid, tocopherol and plastochromanol composition of seed oil (Rogers, 1972; Green, 1984; Velasco and Goffman, 2000) show distinct patterns between sections that support the classical taxonomic treatment of the genus.

Basic chromosome numbers in the genus include $x = 8, 9, 10, 12, 14, 15$ and 16 , with $x = 9$ and $x = 15$ being the most frequently occurring. Cytogenetic studies of interspecific crosses within the $n = 9$ and $n = 15$ groups of species within section *Linum* revealed essentially homologous chromosomes with only a limited number of chromosome translocation differences between species (Gill and Yermanos, 1967a). *L. usitatissimum* has a chromosome number of $2n = 30$ and behaves cytogenetically as a diploid species. It is considered to have originated by an ancient tetraploidy event from the basic $n = 9$ to give rise to $n = 18$, followed by chromosomal reorganization and aneuploidy to $n = 15$ (Gill, 1987). This hypothesis is supported by the regular occurrence in flax of traits controlled by duplicate gene loci, such as those controlling the $\Delta 15$ -desaturase gene in developing seeds (Green, 1986b; Vrinten *et al.*, 2005).

Extensive studies of crosses between flax and other *Linum* species revealed the presence of significant crossability barriers correlated to the sections of the genus (Allan Green, unpublished data). *L. usitatissimum* is separated from other species in section *Linum* by postfertilization barriers that resulted in hybrid embryo degeneration, whereas it is separated from species from other sections by prefertilization barriers, such as failure of pollen germination or rejection of pollen tubes in the style. These prefertilization barriers may be a consequence of the heterostylous self-incompatibility mechanisms that are prevalent in these sections of the genus.

1.4 Conventional Flax Breeding Methods

1.4.1 Selection within existing genetic variation

The flax plant is predominantly self-pollinating, with outcrossing rates generally below 1%, although rates as high as 6% have been reported

for particular genotypes and environments (Robinson, 1937; McGregor, 1976; Free, 1993). Commercial flax varieties are, therefore, usually pure lines developed through a variety of breeding and selection strategies typically employed for self-pollinating crops. In the early 1900s mass selection or single plant selection from within genetically variable accessions was the main way of developing pure line varieties. Subsequently, hybridization of pure lines having complementary traits followed by pedigree selection of desirable recombinant lines from within the segregating progeny became established as the predominant breeding strategy (Culbertson, 1954; Kenaschuk, 1975).

Pedigree selection schemes commence with the intercrossing of inbred lines, followed by selfing of the F_1 hybrid plants to produce a large F_2 seed population. A population of several thousand F_2 plants is then grown in the field, usually on soil that is heavily infected with *Fusarium oxysporum*, the causal organism of flax wilt, which is the major disease of concern for flax in most production regions. Surviving plants are scored for major traits with high heritability, such as flower color, flowering time, and seed color. The selected F_2 plants are subsequently retested in the wilt nursery as F_3 progeny rows to identify homozygous wilt resistant lines. In parallel, F_3 plants may be inoculated with specific strains of flax rust (*Melampsora lini*) under glasshouse conditions to identify rust resistant lines. Seed harvested from selected F_3 lines is used to establish F_4 progeny rows and selection continues. Typically, selection for desirable plant phenotype and performance will begin in the F_4 generation with the harvesting of a number of single plant selections from within each line, along with bulk seed of the whole F_4 line. In the case of oilseed flax, data on seed quality attributes such as oil quality, oil content, and protein content are obtained from samples taken from the bulk seed lots, and used to further truncate the population of desirable lines. In the following F_5 generation, the bulk seed is used to establish replicated small plots to enable between-line selection for seed yield, and the single plant selections are grown as progeny rows. Superior F_5 lines are identified on the basis of yield and quality performance in the replicated plots and sublines of these are used to establish the subsequent F_6 generation. Depending on the genetic divergence between the initial parents, this cycle of

between-line and within-family selection may need to be repeated for another one or two generations until uniform pure lines with elite performance have been derived. Selected pure lines are advanced into multilocation yield trials to compare their performance and adaptability with that of existing cultivars.

Single-seed descent is a popular modification of the pedigree selection that enables the development of recombinant inbred lines to be accelerated. It typically involves harvesting a single capsule per plant from a large F_2 or F_3 plant population (that may have been grown in a wilt nursery). Seed from each capsule is planted in a single pot, grown to maturity under glasshouse conditions, and a single capsule harvested from each pot. This inbreeding cycle is continued until the F_5 or F_6 generation, after which, seed of each line is increased and subsequently evaluated in replicated field plots. This procedure is best suited for crosses between highly adapted parents where the number of inferior offspring lines is expected to be low. The generation cycle time can be further reduced by growing the single-seed descent generations under conditions of high plant density and restricted nutrition, essentially aiming to produce only a few capsules per plant.

The development of inbred lines can be further accelerated through the use of doubled haploid breeding methods, which not only avoid the lengthy process of selfing but also increase the frequency of recombinant genotypes in the resulting population. In flax, haploid plants were first identified as haplo-diplo twins in polyembryonic seeds, which occur at low frequency (<1%) in many cultivars (Rajhathy, 1976) and are readily converted to diploids by chromosome doubling through the application of colchicine to decapitated stems (Plessers, 1965). Green and Salisbury (1983) developed lines with up to 32% haplo-diplo twin seedlings in a cross between cv. Rocket and cv. Avantgarde, creating a highly efficient, though genotype specific, system for doubled haploid generation in flax. More recently, haploid plants have been routinely produced by microspore culture in a less genotype-dependent manner (Chen and Dribnenki, 2004) and this may prove to provide a more broadly applicable system of doubled haploid breeding in flax.

Backcross breeding is useful for the transfer of simply inherited characters from unadapted donor

parents into elite recipient lines with minimum disturbance to the performance (Kenaschuk, 1975). It involves repeated cycles of crossing to the recipient line (recurrent parent) followed by selection for the trait being transferred. Backcross breeding was first used in flax to develop a set of rust differentials by transferring individual rust resistance alleles into the cv. Bison (Flor, 1955). These differentials have been extensively utilized in flax rust research, and as a source of resistance genes for backcrossing into elite flax varieties to overcome their susceptibility to new races of flax rust. More recently, backcross breeding played an important role in the development of the initial low linolenic flax (Linola) varieties. The low linolenic flax mutants (*ln1* and *ln2*) created in the “Zero” genotype following EMS (ethylmethane sulfonate) mutagenesis of the Australian linseed cv. Glenelg (see below) were initially associated with several undesirable background mutations that reduced plant vigor. Four generations of backcrossing the “Zero” genotype to its parent Glenelg fully restored plant performance and resulted in the development of the Linola cv. Eyre (Green and Dribnenki, 1994). Likewise, four generations of backcross breeding was sufficient to introgress the *ln1* and *ln2* mutations and a yellow seed color marker gene into the elite Canadian flax cultivars McGregor and Norlin, to develop the first Canadian Linola cultivars, Linola 947 (Dribnenki and Green, 1995) and Linola 989 (Dribnenki *et al.*, 1996), respectively, with yields equivalent to their recurrent parents.

Recurrent selection is a variation of backcross breeding, where selection for performance is practiced within consecutive segregating progeny generations after the population has been truncated for the major trait being transferred. Several high-performing lines are crossed back to the recurrent parent to initiate another cycle – there can be up to five cycles of hybridization back to the recurrent parent. This strategy allows for the transfer of a major trait, but also provides the possibility of increasing overall performance above that of the recurrent parent through contribution of favorable genes from the donor parent.

The potential value of F_1 hybrid breeding methods in flax is signified by reports of heterosis levels generally in the range of 25–40% (Kumar and Singh, 1970) and as high as 231% in some

crosses (Dubey and Singh, 1969). Although flax was one of the first crops in which an effective genetic system of cytoplasmic male sterility and fertility restoration was identified (Chittenden, 1927; Gairdner, 1929), the system has never been employed for the commercial production of hybrid varieties. The main impediment has been that male-sterile flax flowers generally have closed corollas, which fail to open and thus prevent cross pollination. However, male sterile plants with more open corollas have been reported (Kumar and Singh, 1970; Thompson, 1977) and simulation experiments have shown up to 13% seed set from open-pollination of flax flowers that were emasculated and had their petals removed (Rykova, 1973). Hybrid varieties clearly offer considerable potential for a quantum increase in yield in flax, however, further research is needed before an efficient, productive and cost-effective system of hybrid seed production will be available.

1.4.2 Interspecific hybridization to access genetic variation in related *Linum* species

Interspecific hybridization has occasionally been proposed as a means to access genetic variation in wild *Linum* species, especially where the extent of natural variation within *L. usitatissimum* has been insufficient to achieve flax breeding objectives. For example, flax shows only limited variation for fatty acid composition of the seed oil, being predominantly composed of linolenic acid (45–65%), which prevents the development of new fatty acid profiles by conventional selection (Green and Marshall, 1981). In contrast, wild *Linum* species show a much greater range in composition, including species such as *Linum tenuifolium* having over 80% linoleic acid and only 3% linolenic acid, and *Linum mucronatum* that contains 5% of the hydroxylated ricinoleic acid (Green, 1984). However, *L. usitatissimum* is reproductively isolated from most other *Linum* species by either prefertilization or postfertilization barriers depending on the degree of taxonomic separation of the species (Allan Green, unpublished data). There are no reports of successful rescue of nonviable embryos from interspecific *Linum* hybrids using tissue culture techniques that have been effective in other genera.

To date, fertile interspecific hybrids have only been achieved between flax and a limited number of species that are from the same section of the genus (section *Linum*) and have the same chromosome number ($2n = 30$) including *L. angustifolium*, *L. bienne*, *L. nervosum*, *L. pallescens*, *L. africanum*, *L. corymbiferum*, *L. decumbens*, *L. hirsutum*, *L. floccosum* and *L. tenue* (Gill and Yermanos, 1967b; Bari and Godward, 1970; Seetharam, 1972). Unfortunately all species from the section *Linum* so far analyzed show similar fatty acid composition to flax (Green, 1984) and therefore, do not represent a useful genetic resource for modification of this character. However, it is possible that those closely related species that are accessible by conventional hybridization may harbor other traits that could be useful for flax breeding, such as novel alleles for disease resistance genes, or wider variability for morphological characteristics.

1.4.3 Mutation breeding to create new variation

In situations where there is insufficient genetic variation available to achieve breeding objectives, new genetic variants can often be created by induced mutation techniques, using either physical or chemical mutagenic agents. A wide range of induced mutations have been reported in flax, including those causing chlorophyll deficiencies (Seetharam, 1971a; Rai and Das, 1975), increased oil content (Larter *et al.*, 1965; Rath and Scharf, 1968; Seetharam, 1971b), altered seed weight (Seetharam, 1971b), increased seed yield (Bari, 1971; Srinivasachar *et al.*, 1972), and improved disease resistance (Srinivasachar and Seetharam, 1971). Although useful for basic genetic studies, most of these mutations have not made a significant contribution to flax improvement.

In contrast, mutation breeding has proved highly valuable in generating altered fatty acid composition profiles in flax seed oil (Table 2). Green and Marshall (1984) used EMS-mediated chemical mutagenesis of the Australian linseed cv. Glenelg to produce two independent mutant lines, M1589 and M1722, in which linolenic acid content was reduced from 43% down to 29%. Subsequent recombination of these mutations resulted in

Table 2 Fatty acid composition (% of total fatty acids) of linseed cvs. Glenelg and McGregor and mutants derived from them by EMS mutagenesis

Genotype	Palmitic (16:0)	Palmitoleic (16:1)	Stearic (18:0)	Oleic (18:1)	Linoleic (18:2)	Linolenic (18:3)
Glenelg ^(a)	6		3	19	22	50
M1589 ^(a)	7		4	21	35	33
M1722 ^(a)	6		4	24	33	33

almost complete removal of linolenic acid from the seed oil (down to only 2%), with an equivalent increase in the content of its precursor linoleic acid, up from 14% to 51% (Green, 1986a). Genetic and biochemical analysis revealed that the mutations were in two independent genes (*Ln1* and *Ln2*) that encode the $\Delta 15$ -desaturase enzyme responsible for converting linoleic acid to linolenic acid (Green, 1986b; Tonnet and Green, 1987; Stymne *et al.*, 1992). Similar changes were subsequently reported in the Canadian cv. McGregor by apparently simultaneous EMS-induced mutations in two independent genes (Rowland, 1991), most likely the same genes as were mutated in Glenelg. These genes were subsequently cloned, confirmed to belong to the *Fad3* family of microsomal fatty acid $\Delta 15$ -desaturases and designated as *LuFAD3A* and *LuFAD3B* (Vrinten *et al.*, 2005). The low linolenic mutants obtained in Glenelg were used to create a new form of linseed oil referred to as LinolaTM with greatly improved oxidative stability and suitability for widespread food use, as an alternative to sunflower and safflower oils (Green and Dribnenki, 1994). Linola has become successfully established as a specialty form of flax, especially in Canada where it accounts for a significant proportion of the flax crop.

EMS mutagenesis was successfully used to produce additional variations in fatty acid composition (Table 2) including lines with elevated oleic acid and palmitic acid contents (Rowland and Bhatti, 1990; Rowland, 1991; Saeidi and Rowland,

1997; Allan Green, unpublished data). Mutation breeding is particularly useful for blocking biosynthetic pathways in order to prevent the synthesis of particular compounds. As well as the above changes in fatty acid biosynthesis pathways, mutation breeding may have potential in the future to remove other undesirable compounds from flaxseed, such as cyanogenic glycosides and linatine.

1.4.4 Limitations of conventional breeding methods

Conventional breeding techniques have been employed in flax for over a century and have been particularly successful in equipping the crop with durable resistance to the major wilt and rust diseases, improving lodging resistance, adapting crop phenology to match regional growing seasons, and developing varieties with greater yield stability across environments. However, over recent decades the rate of overall yield improvement in flax has lagged behind that was achieved in other oilseeds, particularly soybean and rapeseed (canola). This is no doubt partly due to the relatively small size of the flax crop globally and the resulting lower resources and attention given to flax improvement. However, the restricted genetic variation within the species, inability to incorporate genetics from related species, and

importantly, the lack of development of hybrid production systems, contribute to the lack of major progress. Mutation breeding has resulted in significant achievements in the diversification of product quality, however, even this technique is limited in its suitability for the further quality improvements needed in the future, and is unlikely to be suitable for achieving significant increases in yield.

Gene technology has proven to be highly successful in improving several oilseed crops, especially through the transgenic introduction of herbicide tolerance and insect resistance genes that allow more effective and cheaper weed and pest control, and the introduction of novel genetic systems for hybrid seed production. These achievements highlight the improvements that can be realized in flax through genetic transformation with similar novel traits. Additionally, many of the future opportunities for development of new and improved products in flax will require metabolic engineering approaches that involve genetic transformation, either by genes that encode functional enzymes for additional biosynthetic pathways, or gene silencing constructs that can restrict the inactivation of unwanted endogenous genes to specific target tissues (e.g., seed for oilseed flax, and stem for fiber flax). Transgenic technologies, therefore, offer substantial potential to achieve improvements in flax that cannot be attained by conventional breeding methods.

2. FLAX TRANSFORMATION

Because flax is a relatively minor crop in global terms, transgenic applications have not been pursued as much as in larger crops (e.g., maize, soybean, canola, cotton). However, flax has proved to be very amenable to genetic transformation and some novel agronomic (input) traits, such as herbicide tolerances, initially developed in other crops, have now been transferred to flax. In addition, new and improved product quality (output) traits specific for flax have been pursued, including attempts to modify stem fiber quality of fiber flax varieties and to diversify oil composition in oilseed flax (linseed) varieties (Table 3).

2.1 Transgenic Traits Developed

2.1.1 Herbicide tolerance

The first trait engineered into flax was tolerance to the herbicide glyphosate (Roundup[®]), a potent inhibitor of the enzyme 5-enolpyruvylshikimate-3-phosphate (EPSP) synthase in higher plants. A gene encoding a glyphosate-insensitive form of the EPSP enzyme cloned from a complementary DNA library of a glyphosate-tolerant *Petunia hybrida* cell line (MP4-G) was shown to confer glyphosate tolerance to normally sensitive *Petunia* cells when expressed transgenically under the control of the constitutive cauliflower mosaic virus 35S promoter (Shah *et al.*, 1986). Subsequently, this *EPSP* gene was transformed into flax by *Agrobacterium*-mediated transformation and the resulting transgenic flax lines were shown to be resistant to 5 mM glyphosate (Jordan and McHughen, 1988a).

Subsequently, genes encoding tolerance to other herbicides were developed and successfully introduced into flax. A mutant acetolactate synthase gene isolated from *Arabidopsis* was shown to confer tolerance to the sulfonylurea herbicide chlorsulfuron (Glean[®], DuPont) in plants (Haughn *et al.*, 1988). Transfer of this gene under the control of the native *Arabidopsis* regulatory signals to flax led to the development of lines with chlorsulfuron tolerance. Transgenic lines grew vigorously in soil containing 20 g ha⁻¹ chlorsulfuron whereas the growth and development of the untransformed control were severely inhibited (McHughen, 1989). Transgenic flax plants have also been developed to have tolerance to bialaphos, a broad-spectrum antibiotic based herbicide marketed as Basta[®] and Liberty[®] (AgrEvo). This was achieved by introduction of the phosphinothricin acetyl transferase (PAT) gene from *Streptomyces viridochromogenes* under the control of cauliflower mosaic virus (CaMV) 35S promoter. The introduction of the PAT enzyme allows the flax plants to breakdown glufosinate ammonium herbicide, applied at the level of 600 g ha⁻¹, without suffering any toxic effects (McHughen and Holm, 1995a).

The bialaphos and chlorsulfuron tolerant flax lines were evaluated in field trials and the introduced traits were shown to perform well under field conditions and to incur no agronomic

penalties to the crop (McHughen and Holm, 1995b). Submissions were made to US FDA (Food and Drug Administration) for release of the chlorsulfuron-tolerant variety “Triffid”, however, due to sustained pressure from the Flax Council of Canada and resistance from EU customers the variety was removed from the market in 2001.

2.1.2 Fiber quality

The use of flax fibers in textile industries has been in decline due to severe challenge from cotton and synthetic polymers. In order to enhance the thermoplastic properties of flax fibers, transgenic plants synthesizing polyhydroxybutyrate (PHB) in their stem tissue have been generated. PHB is a nontoxic biodegradable thermoplastic agent that is soluble in water and has similar chemical and physical properties to the petroleum-derived polymer polypropylene. In various species of bacteria, for example, *Ralstonia eutropha*, PHB acts as a source of carbon and energy and is synthesized by the concerted action of 3-ketothiolase, acetoacetyl-CoA reductase, and PHB synthase enzymes. Wrobel *et al.* (2004) transformed flax with the three genes, isolated from *R. eutropha*, encoding these enzymes. The genes were expressed under the control of a stem-specific promoter (14-3-3, GenBank Acc No: AY070220) and were targeted to the plastid to avoid possible deleterious effects of PHB accumulation. The transgenic flax plants were shown to accumulate up to 70-fold higher PHB than nontransgenic flax and were shown to display significant modifications in stem mechanical properties. For example the Young’s modulus E , an average measure of stem tissues resistance to tensile loads, increased up to twofold

in transgenic plants producing PHB than in non-PHB containing controls.

2.1.3 Oil quality

ω -3 long-chain polyunsaturated fatty acids (ω 3 LC-PUFA), such as EPA (eicosapentaenoic acid, C20:5) and DHA (docosahexaenoic acid, C22:6) and are now widely recognized as having important benefits for human health. Whilst the human body is capable of synthesizing them from dietary α -linolenic acid (ALA, C18:3 $\Delta^{9,12,15}$), the conversion rate is very inefficient (Voss *et al.*, 1991) and direct dietary intake of EPA and DHA is therefore recommended for good nutrition. Fish are the current principal sources of these fatty acids, but fish supplies are diminishing and novel sources of EPA and DHA are being sought. EPA and DHA are synthesized by a variety of microorganisms and lower plants, but they are not naturally produced in higher plants. Because flaxseed is one of the richest sources of ALA, it has been regarded as an attractive starting point for genetic engineering to produce a plant source of EPA and DHA.

Metabolic engineering of yeast and higher plants to produce EPA and/or DHA has recently been attempted using genes from organisms that naturally synthesize and accumulate LC-PUFA by a series of alternating elongation and desaturation reactions. Seed-specific expression in flax of cDNAs encoding a set of front-end fatty acid desaturases and a $\Delta 6$ fatty acid elongase (Abbadi *et al.*, 2004) resulted in significant $\Delta 6$ -desaturation of ALA to form stearidonic acid (C18:4) and to a much lesser degree, further elongation and $\Delta 5$ -desaturation to EPA. Additionally, two $\omega 6$ LC-PUFA, γ -linolenic acid

(GLA, C18:3^{Δ6,9,12}) and arachidonic acid (ARA, C20:4^{Δ5,8,11,14}) were synthesized as a result of the action of the same introduced enzymes on linoleic acid (LA, C18:2^{Δ9,12}). Whilst the levels of EPA synthesized were only low in this experiment, recent developments in the area of engineering LC-PUFA in other oilseeds are promising for the eventual development of flax oil with substantially higher amounts of nutritionally important ω 3 LC-PUFA (Napier *et al.*, 2006).

2.2 Transformation Methods

The successful regeneration of transgenic plants requires an effective DNA delivery system to transfer the gene of interest into the cells of the target explants and an efficient, reproducible system to regenerate plants from the transformed cells. The four most established DNA delivery systems are mediated by either *Agrobacterium*, polyethylene glycol (PEG), particle bombardment, or microinjection (Potrykus, 1991). Three of these approaches have been successfully adopted in *Linum* species to regenerate transgenic plants. The first demonstration of successful integration of transfer DNA (T-DNA) into the flax genome was reported in 1983 and involved the transformation of flax epicotyls by a nopaline strain of *Agrobacterium tumefaciens* T37 harboring an oncogenic plasmid pTi37 (Hepburn *et al.*, 1983). Four years later, the first successful regeneration of transgenic flax plants was reported. In that study, flax hypocotyl segments were transformed with another nopaline *A. tumefaciens* strain C58C1 carrying a disarmed (nononcogenic) Ti plasmid vector pGV3850 (Basiran *et al.*, 1987).

One year later, transgenic flax plants were regenerated from transformation of cotyledons with various *A. rhizogenes* strains A4, 1855 and TR7 containing root-inducing (Ri) plasmid pRiA4, pRi1855, and pRiTR7, respectively (Zhan *et al.*, 1988). In order to overcome some of the problems encountered with *Agrobacterium*-mediated transformation techniques and capitalize on the efficient protoplast culture system, direct transformation of protoplast of *Linum suffruticosum* mediated with PEG was developed and transgenic plants were regenerated (Ling and Binding, 1997). In order to develop a rapid and simple means of transforming intact cells and tissues, particle bombardment-mediated transformation technique was also established (Wijayanto and McHughen, 1999).

Subsequently research efforts in different laboratories around the world have been primarily focused on *A. tumefaciens*-mediated transformation due to the potential for high transformation efficiency and production of transgenic plants with simple transgene insertion patterns and high stability of the transgene in the progeny (Jordan and McHughen, 1988a; Mlynarova *et al.*, 1994; Bretagne-Sagnard and Chupeau, 1996; Chen and Dribnenki, 2003). Since the processing and transfer of T-DNA from *Agrobacterium* to plant cells have been demonstrated to be regulated by the activity of the *vir* genes located in the resident Ti plasmid and by the specific interactions between Ti plasmid and *Agrobacterium* chromosomal background (Gelvin, 2003), various types of *Agrobacterium* strains, including octopine, nopaline, and succinamopine type strains have been tested in flax in different laboratories (Table 4). However, no experiments have been designed

Table 4 Type of *Agrobacterium* strains used in flax transformation

to directly compare the effect of *Agrobacterium* strains on transformation in flax. In one study, two *Agrobacterium* strains, AGL1 and C58C1 Rif[®] (pGV2260), were used but the binary vector introduced into AGL1 carried a spectinomycin resistance gene, whereas that introduced into C58C1 Rif[®] carried a kanamycin resistance gene. The conclusion from that study was that spectinomycin was a more effective selective agent than kanamycin for flax (Bretagne-Sagnard and Chupeau, 1996). However, the strain differences may have also contributed to the different transformation efficiencies obtained.

Agrobacterium cell density at time of co-cultivation appears to have significant effect on shoot regeneration and transformation. Co-cultivation of explants with *Agrobacterium* strain AGL1 at OD₆₀₀ of 1.2 had more prevalent overgrowth, resulting in lower frequency of shoot regeneration and lower efficiency of transformation than co-cultivation at OD₆₀₀ of 0.3 (Chen and Dribnenki, 2003). Because activity of the *vir* genes present on the resident plasmid of an *Agrobacterium* strain have been shown to be induced by wounding or phenolic compounds such as acetosyringone and related molecules (Stachel *et al.*, 1985), application of these phenolic compounds have been used to increase transformation efficiency of some crop species (De Clercq *et al.*, 2002; Hoque *et al.*, 2005). However, different Ti plasmid, plant species and plant tissues have been shown to require different levels or different types of phenolic compounds for optimal induction of the *vir* genes (Messens *et al.*, 1990). Although sinapinic acid had been shown to specifically activate the *vir* region of the Ti plasmid (Stachel *et al.*, 1985), there was no noticeable effect observed in flax when it was added to the growth medium for *A. tumefaciens* strain C58C1 before co-cultivation at concentration of 100–200 μ M (Zhan *et al.*, 1988). Likewise, the addition of acetosyringone at concentrations from 50 to 200 μ M to co-cultivation medium with AGL1 did not increase transformation efficiency in comparison with co-cultivation medium containing no acetosyringone (Chen *et al.*, 2008). Co-integrative transformation vector systems were used in earlier research experiments (Basiran *et al.*, 1987; Zhan *et al.*, 1988; Jordan and McHughen, 1988a), however, more recent studies have almost exclusively used

binary vector systems (Dong and McHughen, 1993a; Mlynarova *et al.*, 1994; Bretagne-Sagnard and Chupeau, 1996; Chen and Dribnenki, 2003).

2.3 Selection of Transformed Tissue

Regardless of which DNA delivery system is used, it is crucial to have an effective system for selecting the limited number of transformed cells from amongst an overwhelmingly larger number of nontransformed cells. The ideal selection condition is to achieve the optimal growth of transformants and minimal survival of non-transformants. Antibiotic or herbicide resistance conferred by selectable marker gene has commonly been used for this purpose. In *Agrobacterium*-mediated transformation, additional antibiotics, such as carbenicillin, augmentin, timentin, or cefotaxime are used to kill the *Agrobacterium* after a period of co-cultivation with explants.

The first transgenic flax plants were regenerated from transformed cells expressing the selectable marker gene *nptII* (neomycin phospho-transferase II), which confers resistance to aminoglycoside antibiotics, such as kanamycin (Basiran *et al.*, 1987). This selectable marker gene has since been used in many transformation studies and other selectable marker systems have also been developed (Table 5). For *nptII* selectable marker, other aminoglycoside antibiotics, such as geneticin (G418) and paromomycin besides kanamycin, have been used as the selective agents in the selection medium (Dong and McHughen, 1993a; Bretagne-Sagnard and Chupeau, 1996). Compared to kanamycin, lower concentrations of geneticin are needed to kill nontransformed shoots. However, kanamycin at concentrations from 50 to 200 mg l⁻¹ proved to be more effective in selecting transformed shoots than geneticin (Dong and McHughen, 1993a). Paramomycin was not an effective selective agent for flax as concentration up to 200 mg l⁻¹ failed to inhibit shoot regeneration from untransformed cells (Bretagne-Sagnard and Chupeau, 1996). Despite successful reports of using *nptII* as the selectable marker, some laboratories have reported difficulty in regenerating transgenic plants using kanamycin as the selection agent in the medium (Zhan *et al.*, 1988; Bretagne-Sagnard and Chupeau, 1996). In those studies, thousands or tens of thousands of

explants were inoculated with the same strain of *Agrobacterium* containing the same vectors that have been reported to produce transgenic shoots in flax. The difference in genotype of explants and transformation protocol may partially account for the difficulty encountered with these two reports. Alternatively, this may indicate that kanamycin is a problematic antibiotic to work with in flax perhaps due to poor penetration to the regenerating cells (Bretagne-Sagnard and Chupeau, 1996).

Subsequently, the selectable marker gene *aadA* encoding the enzyme aminoglycoside-3'-adenyltransferase, which confers resistance to a structurally unique aminocyclitol antibiotic spectinomycin, has been successfully used in selecting transformed flax cells and plants. Selection concentration of spectinomycin at 50–100 mg l⁻¹ proved to be effective (Bretagne-Sagnard and Chupeau, 1996; Chen *et al.*, 2008). Spectinomycin appears to be more mobile than kanamycin and thus is spread more homogeneously among the transformed tissue, which makes for more accurate and effective selection (Bretagne-Sagnard and Chupeau, 1996).

The third antibiotic resistance selectable marker system developed in flax transformation was *hph* or *hpt* encoding the enzyme hygromycin B phosphotransferase, which confers resistance to aminoglycoside antibiotic hygromycin B. This selectable marker has been successfully used to obtain transformed cells and plants from protoplasts, hypocotyl explants and anther cultures. Selection at concentrations from 5 to 30 mg l⁻¹ hygromycin B proved to be effective in various experiments in different laboratories (Ling and Binding, 1997; Rakousky *et al.*, 1999; Chen and Dribnenki, 2003).

The incorporation of antibiotic resistance genes in commercial transgenic plants has come to be regarded as undesirable due to public perceptions

that it could accelerate the development of antibiotic resistant microorganisms. Herbicide resistance may, therefore, be a better choice than antibiotic resistance. In earlier studies, antibiotic resistance selection was used to select transformed cells for the expression of herbicide resistant traits, such as glyphosate resistance conferred by the expression of 5-enolpyruvylshikimate-3-phosphate (*eps*) synthase gene (Jordan and McHughen, 1988a) or sulfonylurea herbicide resistance encoded by a modified acetolactate synthase (*als*) gene (McHughen, 1989). Resistance to the herbicide phosphinothricin (10 mg l⁻¹) was used to select transformed cells and shoots that expressed phosphinothricin acetyltransferase gene (*pat*) in addition to antibiotic resistance selection (McHughen and Holm, 1995a).

The level of selectable agents in selection medium has a significant effect on transformation efficiency and escape frequency. Dong and McHughen (1993a) demonstrated that increase in kanamycin concentration from 50 mg/l to 200 mg/l in selection medium reduced the total number of shoots regenerated, but increased the total number of explants producing transgenic shoots and the total number of transgenic shoots. This was an ideal situation since high selection pressure reduced the laborious effort to identify true transgenic plants within a large population of regenerated shoots encountered with low selection pressure. However, selection at too high concentration or for an extended period of time can eventually reduce recovery of transgenic plants since regeneration from transformed cells, particularly those expressed at low-to-moderate levels, could be inhibited. Selection at 10 mg l⁻¹ hygromycin B in callus induction medium for 2 weeks before transfer to a shoot regeneration medium had higher frequency

of shoot regeneration and greater efficiency of transformation than the selection for 4 weeks (Chen and Dribnenki, 2003).

2.4 Plant Regeneration

2.4.1 Hypocotyl explant culture

An efficient plant regeneration system is a prerequisite for the development of an efficient transformation system regardless of DNA delivery methods used. The first successful *in vitro* regeneration of flax plants from cultured explants was reported over 30 years ago (Rybczynski, 1975; Gamborg and Shyluk, 1976). A range of different types of cultured explants have subsequently proven to be amenable to regeneration, either directly or through an intermediate callus phase, with hypocotyl segments being more easily regenerated than other tissues (Mathews and Narayanaswamy, 1976; Bretagne *et al.*, 1994; Dedicova *et al.*, 2000). Not surprisingly, the first successful regeneration of transgenic plants was achieved using hypocotyl segments as the explants for co-cultivation with *Agrobacterium* (Basiran *et al.*, 1987). Transgenic plants have since been regenerated from various explant types, including cotyledons, protoplasts, plastocytes, and anther cultures (Zhan *et al.*, 1988; Ling and Binding, 1997; Chen and Dribnenki, 2003). However, scientists are challenged to develop reproducible transformation protocols as the initial protocols developed in one laboratory could not easily be reproduced in other laboratories.

In the first report, hypocotyl segments were transformed by an *Agrobacterium* strain harboring a vector containing a chimeric *nptII* gene as a selectable marker and the nopaline synthase gene as a scorable trait. Transgenic status of kanamycin resistant calli was determined by Southern analysis, nopaline production and NPTII activity. The transgenic status of shoots regenerating from resistant calli was only demonstrated by nopaline production in these shoots and by their rooting ability in medium containing kanamycin, with no molecular analysis or progeny analysis being conducted on these plants (Basiran *et al.*, 1987). The same *Agrobacterium* strain C58C1 harboring the same disarmed Ti plasmid pGV3850 with the same *nptII* selectable marker gene

as Basiran *et al.* (1987) was used in another study where several thousand hypocotyl segments were used as explants for co-cultivation (Zhan *et al.*, 1988). Transgenic status of kanamycin resistant calli appearing on the cut ends of inoculated hypocotyl segments were demonstrated by Southern analysis and nopaline production. Nopaline production was detected in both bleached and green shoots appeared on kanamycin resistant calli, and Southern analysis of DNA from two of the shoots which were produced in kanamycin containing medium showed that they were not transformed (Zhan *et al.*, 1988). Such nontransformed regenerants were considered to have been derived from nontransformed cells that had survived exposure to the selection agent by cross-protection from adjacent transformed cells (Jordan and McHughen, 1988b). The different results observed between the early study by Basiran *et al.* (1987) and these two subsequent studies by Zhan *et al.* (1988) and Jordan and McHughen (1988b) might be explained by the differences in genotype of explants since almost identical medium and tissue culture procedure were used. Jordan and McHughen (1988a) were able to regenerate true transgenic flax plants when hypocotyl segments were sliced along the top surface, or where strips of epidermis were removed from hypocotyl segments before co-cultivation with *Agrobacterium*. In that study, transgenic status of regenerated plants was confirmed by a leaf callus assay on medium containing the selective agent, nopaline assay on leaf-derived calli, and transmission of selectable marker gene and gene of interest to the next generation (Jordan and McHughen, 1988a). This transformation protocol proved to be repeatable in the same laboratory and was further improved by including the additional step of preculture of hypocotyl segments for a period of time before co-cultivation (McHughen *et al.*, 1989). A preculture period of 9–12 days prior to co-cultivation was found to be optimal for recovery of transgenic shoots. The beneficial effect of preculture was considered to be due to the physiological and developmental shift of hypocotyl cells to become competent for regeneration during the preculture period (McHughen *et al.*, 1989). This improved transformation protocol was used to produce transgenic plants conferring sulfonylurea herbicide resistance (McHughen, 1989). The first report of molecular

analysis of primary transformants was in the study of Dong and McHughen (1993a) where transgenic status of primary transformants was confirmed by polymerase chain reaction (PCR) amplification of antibiotic selectable marker *nptII* gene and by histochemical assay and progeny analysis of the scorable marker gene *gusA* that encodes β -glucuronidase (GUS). Under optimal conditions, transformation efficiency defined as the percentage of independent explants producing at least one transgenic shoot was 13%, and escape frequency defined as the percentage of nontransgenic shoots surviving the selection process was 83% (Dong and McHughen, 1993a). Chimera frequency defined as the percentage of putative transformants showing less than expected transgene positive plant and more than expected transgene negative plants in progeny analysis was approximately 45% (Dong and McHughen, 1993b). The high escape frequency could result from the cross protection of a large number of nontransformed shoots of epidermal origin by transformed callus tissues at the cut ends (Jordan and McHughen, 1988b). Regeneration from cells on the boundaries of peeled and unpeeled region of hypocotyls segments was proposed as the reason for producing high frequency of chimera (Dong and McHughen, 1993b). This study provided the most complete picture regarding overall transformation efficiency since it included transformation efficiency, escape frequency, and escape frequency with a reasonable number of explants for initial co-cultivation with *Agrobacterium*. However, this transformation protocol has a number of drawbacks including tedious and laborious removal of epidermis from hypocotyl segments under the microscope in a flowhood, high frequency of escapes in regenerated plants, and high frequency of chimera in putative transformants. In an effort to overcome the problems encountered with previous protocols, Mlynarova *et al.* (1994) isolated calli formed on the surface of the hypocotyl segments and placed them on fresh selection medium for shoot regeneration. This tedious removal of calli from each hypocotyl segment may help to reduce direct regeneration of plants from epidermal cells and thereby potentially reduce escapes. This could potentially reduce chimera frequency as this protocol does not include the process of epidermis stripping from the explants. The transformation efficiency of about 25% was an improvement over the previous report

by Dong and McHughen (1993a) of 16% based on the number of transgenic shoots obtained per inoculated explant. However, the calculation by Mlynarova *et al.* (1994) was based on GUS activity and PCR analysis of primary transformants, with no progeny analysis conducted. The number of explants used for this study was low and there was no data regarding escape and chimera frequency. In addition, calculation of transformation efficiency based on number of transgenic plants without Southern analysis to determine the independent status of plants is usually an overestimate of true transformation efficiency as some of them are clones due to callus fragmentation and handling errors. Despite the successful results of these reports, Bretagne-Sagnard and Chupeau (1996) were not able to produce any transgenic plants with or without preculture and epidermis removal when over 25 000 hypocotyl segments were inoculated with C58C1Rif[®] (pGV2260) harboring the binary vector p35SGUSINT, the same construct used by Dong and McHughen (1993a). They were however successful in regenerating transgenic plants at the transformation efficiency of around 15–20% when spectinomycin was used as the selective agent in the medium. Transgenic plants derived from transformation of hypocotyl segments with *A. tumefaciens* were characterized by Southern analysis for the first time in flax and progeny analysis was also followed (Bretagne-Sagnard and Chupeau, 1996). Chimera frequency was low based on analysis of a limited number of putative transgenic plants. However, escape frequency was not discussed in that study (Bretagne-Sagnard and Chupeau, 1996). Further modification of transformation using hypocotyl segments as the explants was the development of particle bombardment-mediated DNA delivery system. Particle bombardment mediated-transformation of hypocotyl segments reduced escape frequency and chimera frequency to a certain degree, but transformation efficiency was lower than that in *Agrobacterium* mediated-transformation (Wijayanto and McHughen, 1999).

2.4.2 Cotyledon culture

Even though cotyledons were the first cultured explants to regenerate *in vitro* plants (Rybczynski,

1975), there has been little transformation research with cotyledons as the explants due to technical difficulty to regenerate in subsequent studies (Bretagne *et al.*, 1994; Dedicova *et al.*, 2000). Successful regeneration of transgenic plants as demonstrated by Southern analysis was achieved by co-cultivation of cotyledons with *A. rhizogenes* in one report (Zhan *et al.*, 1988). But there is no report regarding successful transformation of cotyledon explants with *A. tumefaciens*. Development of an efficient transformation protocol using cotyledons as the explants might be possible since high frequency of shoot regeneration from cotyledon explants was recently reported (Rutkowska-Krause *et al.*, 2003).

2.4.3 Protoplast culture

The first successful regeneration of flax plants from protoplast culture was achieved in 1983 (Barakat and Cocking, 1983). The regeneration of transgenic plants from protoplasts by PEG-mediated transformation or plastocytes co-cultivated with *A. tumefaciens* was obtained 14 years later (Ling and Binding, 1997). *Agrobacterium*-mediated transformation of plastocytes apparently reduced escape frequency but its transformation efficiency was much lower than transformation using hypocotyl segments as the explants due to inefficient plant regeneration from transformed calli (Ling and Binding, 1997).

2.4.4 Anther culture

Successful shoot regeneration from anther culture was initially reported in fiber flax (Sun, 1979) and later in oil flax (Nichterlein *et al.*, 1991; Chen *et al.*, 1998a). Anther culture protocol

was subsequently optimized for doubled haploid production and transformation (Chen *et al.*, 1998b, 2003; Chen and Dribnenki, 2002, 2004). A high throughput transformation protocol was developed in flax using anther cultures as the recipient explants. Transgenic status of plants was confirmed by PCR analysis of selectable marker genes, histochemical analysis of a reporter gene, and progeny analysis. Under optimal conditions, transformation efficiency, defined as number of independent calli producing at least one transgenic shoot, was 66%, with escape frequency of 27%, and chimera frequency of 8% (Chen and Dribnenki, 2003). More recently, hundreds of transgenic plants derived from several independent experiments were analyzed by Southern analysis to determine the independent status of transgenic plants from the same callus and integration pattern of transgene. Transformation efficiency based on the number of independent shoots/per inoculated explant was at least twice as much as that calculated based on the number of independent calli producing at least one transgenic shoot per inoculated explant (Chen *et al.*, 2008). This transformation protocol represents a significant improvement over any other published transformation protocols for all transformation parameters: transformation efficiency and escape frequency (Table 6), as well as chimera frequency (Table 8).

2.5 Transformation Stability

In earlier studies of flax transformation, opine expression, rooting of shoots, and positive leaf callus assay on medium containing a selective agent followed sometimes by progeny analysis were used independently and in combination to provide the evidence of transformation (Basiran *et al.*,

Table 6 Transformation efficiency and escape frequency in flax transformation

Study	Transformation efficiency (%)	Escape frequency (%)
Dong and McHughen, 1993a ^(a)	13	83
Mlynarova <i>et al.</i> , 1994 ^(b)	25	60
Bretagne-Sagnard and Chupeau, 1996 ^(b)	15	NA
Chen and Dribnenki, 2003 ^(a)	66	27

^(a)Transformation efficiency was defined as the number of independent explants producing at least one transgenic shoot/100 inoculated explants

^(b)Transformation efficiency was defined as the number of transgenic shoots obtained per 100 inoculated explants

Anther cultures	1–7	Chen <i>et al.</i> , 2008

1987; Jordan and McHughen, 1988a; McHughen, 1989). Subsequently, PCR analysis of the selectable marker gene and the reporter gene was used to confirm the physical presence of the transgene in the flax genome (Dong and McHughen, 1993a; Mlynarova *et al.*, 1994). Variation in transgene expression within the population of transgenic plants transformed with the same construct and the same transformation experiment has often been encountered (Luck *et al.*, 2000; Qiu *et al.*, 2002; Abbadi *et al.*, 2004; Chen *et al.*, 2008). The factors that have been used to explain this phenomenon in other species include transgene copy number, the position within the genome where transgene is integrated (Matzke and Matzke, 1998), transcriptional gene silencing, or post-transcriptional gene silencing due to the presence of complex integration patterns such as tandem repeats or inverted repeats (Jorgensen *et al.*, 1996; Wang and Waterhouse, 2000) and occurrence of somaclonal variations induced by the tissue culture process. However, the underlying mechanism responsible for the variations in transgene expression observed in flax transformation has not been investigated in detail. Southern analysis of primary transformants was not conducted in some earlier studies due to the technical difficulty (Jordan and McHughen, 1988a; McHughen, 1989). In the few publications where Southern analyses were conducted (Table 7) the correlation between transgene copy number and the level of transgene expression was not established. In a transformation of hypocotyl segments with *A. tumefaciens* using spectinomycin

as the selective agent, it was estimated that between one and six copies of the spectinomycin resistance gene were present in the different transgenic plants analyzed, but the proportion of single copy transformation events was not reported (Bretagne-Sagnard and Chupeau, 1996). Ling and Binding (1997) found that one of four transgenic plants derived from *A. tumefaciens*-mediated transformation of plastocytes had a single insert and that the remaining three plants had two inserts. In a study to evaluate putative seed-specific promoters for *L. usitatissimum*, Drexler *et al.* (2003) reported that most of the transformants had 1–3 copies of the transgene whereas some plants had up to 7 or 8 copies of transgene. In the process of evaluating the anther culture-based high throughput transformation system, approximately 800 transgenic plants from several independent experiments were examined and it was found that insert number ranged from 1 to 7 in different transgenic plants (Chen *et al.*, 2008). Approximately 77% of transgenic plants analyzed had low Southern insert number (1–3) of which about 46% of them had a single Southern insert. Based on Southern analysis, it is estimated that 84% of the plants with single Southern insert were vector backbone free (Chen *et al.*, 2008).

The proof of transmission and stable expression of transgene is the expression of the transgene in the seed progeny (Table 8). In one early study, progeny analysis of 11 transgenic chlorsulfuron-resistant plants derived from flax cv. Norlin using kanamycin as the selectable agent showed that 7 of

Table 8 Inheritance of transgene in transgenic flax

No. of plants	1 locus	2 loci	Homozygous or >2 loci	Chimera	References
11	7 (64%)	1 (9%)	0	3 (27%)	McSheffrey <i>et al.</i> , 1992
22	9 (41%)	2 (9%)	1 (5%)	10 (46%)	Dong and McHughen, 1993b
8	6 (75%)	2 (25%)	0	0	Bretagne-Sagnard and Chupeau, 1996
24	17 (71%)	3 (13%)	2 (8%)	2 (8%)	Chen and Dribnenki, 2003

them (64%) had a single effective transgene locus, 1 of them (9%) had two independent effective transgene loci, and the remaining 3 plants (27%) were chimeric (McSheffrey *et al.*, 1992). However, progeny population analyzed in this study was small (all under 35 seeds). In a subsequent study from the same laboratory using a large progeny population, progeny analysis of 22 transgenic plants derived from the same cultivar using the same selection agent showed that only 9 of them (41%) had a single effective transgene locus and 2 of them (9%) had two independent effective transgene loci. One of them (5%) had multiple transgene loci or transgenes integrated at the same locus of two homologous chromosomes and remaining 10 plants (46%) were chimeras (Dong and McHughen, 1993b). A study from a different laboratory using spectinomycin as the selectable agent showed that 6 of 8 transgenic plants (75%) had a single effective transgene locus and the other 2 plants (25%) had two independent effective transgene loci (Bretagne-Sagnard and Chupeau, 1996). In a more recent study, from a total of 24 transgenic plants derived from transformation using hygromycin as the selective agent, 17 of them (71%) had a single effective transgene locus, 3 of them (13%) had two independent effective transgene loci, 2 of them (8%) had transgenes in the homozygous state, and the remaining 2 were chimeras (Chen and Dribnenki, 2003).

Introduction and expression of a transgene could theoretically lead to diversion of energy that plants would otherwise use to drive other physiological or biochemical processes, and might therefore be capable of impacting on overall yield. However, the expression of various transgenes encoding herbicide tolerance, novel fatty acids or additional disease resistance do not appear to have any obvious phenotypic effect on plant growth and development when the transgenic flax plants are cultivated under growthroom conditions (McHughen, 1989; Qiu *et al.*, 2002; Chen *et al.*, 2008). However, the most convincing results regarding the effect of transgene on plant growth, yield, and quality would be the field evaluation of transgenic lines along with their nontransformed parental line in replicated trials in multiple geographic locations across multiple years. Field test results showed that expression of the mutant *Arabidopsis ALS* gene under the control of the native promoter in flax had

minimal effect on agronomic performance and quality traits including plant height, days to flower, time to maturity, degree of lodging, oil content and quality, 1000-seed weight, and seed yield (McHughen and Rowland, 1991). Based on the stability of transgene expression and comparable agronomic and quality attributes of transgenic line and nontransformed parental line and other check cultivars in field trials, sulfonylurea resistance line 12 115 that expressed a modified acetolactate synthase was registered as CDC Triffid (McHughen *et al.*, 1997). This cultivar was granted unrestricted environmental release in Canada and animal feed use in May 1996 (www.inspection.gc.ca/english/plaveg/pbo/dd9824e.shtml) and human food approval in February 1998 (Health Canada, 1998).

2.6 Regulatory Measures
